A Additional Information about the Platform and Sample

Here we provide additional information and descriptive statistics about the sample and platform.

Firm sample: We listed a representative sample of 10,000 firms across the metropolitan area, using a similar approach as described in Section 2.3 for individual respondents, i.e., a cluster-randomized selection of enumeration areas followed by a listing of all firms in each selected block. A team of enumerators presents the Job Talash service to firms, offering them the opportunity to enroll to list vacancies immediately or later. We also promote the service publicly and include firms who self-select to sign up. Approximately 1,200 firms have signed up across these two samples. The majority of firms responding across both channels have never advertised jobs on any public platform and usually recruit through networks. These firms are recontacted several times a year to invite them to post additional vacancies on the platform. Any firm can also call Job Talash to post a job at any time. Approximately 20 firms post jobs with the service per month, with approximately half posting at least one job over the course of the experiment.

Jobseeker sample: We use secondary data to compare our experimental samples of jobseekers and job ads to representative samples. Table A.1 compares our experimental sample of jobseekers (column 5) and all respondents in our household listing exercise (column 4) to data from Pakistan’s Labor Force Survey for the entire country (column 1), the city of Lahore (column 2), and the city of Lahore reweighted to match the distribution of age, gender, and education as the experimental sample (column 3). Figure A.1 compares the distribution of salaries for vacancies posted on the platform to the distribution of salaries for the Lahore subsample of Pakistan’s Labor Force Survey (Pakistan Bureau of Statistics, 2018-2019). These distributions should be compared with caution, as the former covers vacancies and the latter covers filled jobs, including jobs where incumbent workers have substantial experience with that firm.

Platform information: Table A.2 compares the processes on Job Talash for registering, being notified about matched jobs, and applying for jobs to three other prominent job search platforms. This shows substantial overlap in the processes for learning about matched jobs and submitting applications to these jobs. The other three platforms also include search functions that allow users to learn about jobs outside the match notification system. Table A.3 compares the average monthly job application rate on this platform to other platforms studied by economists that report comparable statistics. This shows that the job application rate on Job Talash is comparable to some other job search platforms. All of the studies reporting the highest application rates consider only “active” platform users, rather than all users.

Figure A.2 shows a sample text message sent to jobseekers. Figure A.3 shows the exact communication process between the platform and jobseekers in the treatment and control groups, including the structure of the script for phone calls.

Table A.1: Summary Statistics for Experimental and External Comparison Samples

Panel A: Full Sample					
	LFS Pakistan	LFS Lahore	LFS Lahore Reweighted	HH Listing Sample	Experimental Sample
	(1)	(2)	(3)	(4)	(5)
Female	0.511	0.493	0.315	0.496	0.315

Registered with an employment agency	0.002	0.001	0.002	N/A	0.032
Took other steps	0.003	0.005	0.004	N/A	0.005

Notes: Table compares the sample of jobseekers in this study (column 5) to several external benchmarks: the country (column 1), Lahore district, where the study takes place (column 2), and people in Lahore in the eligible age range for the study, reweighted with propensity scores to approximate the experimental sample on age, education, and sex (column 3). The table also compares the jobseekers in this study (column 5) to an internal benchmark, the Lahore representative household listing from which the experimental sample was recruited (column 4). The external benchmarks are calculated from the Labour Force Survey (LFS) 2018 using post-stratification weights provided by Pakistan Bureau of Statistics. Standard deviations are shown in parentheses for all continuous variables. Cells with 'N/A' mean that measure was not collected for that sample. The LFS only asked non-employed respondents about search.

Figure A.1: Salary Distribution for Experimental and External Comparison Sample

Notes: Figure shows the distribution of monthly salaries reported in the Labor Force Survey for Lahore in 2018 (red distribution, slightly to the right) and the distribution of salaries for vacancies posted on the platform (blue distribution, slightly to the left). Salary values greater than 200,000 have been top-coded at 200,000. Salaries are reported in Pakistani Rupees per month. 1 Rupee $\approx$ USD 0.03 in purchasing power parity terms during the study period.

Table A.2: Registration and Job Application Processes on Job Talash and Other Job Search Platforms

Platform	Job Talash (control group)	LinkedIn	Rozee	Indeed
Registration process	Complete phone call with the platform that asks about demographics, education, work experience, and occupational preferences. No fee for registration.	Complete registration on the website that requires contact information, location, education, and occupation preferences, with the option of adding more information later. No fee for registration. Can upload CV.	Complete registration on the website that requires contact information, gender, education, work experience, and occupation preferences. No fee for registration. Can upload CV.	Complete registration on the website that requires contact information, location, and gender. Can also provide information on education, work experience, and skills or upload a CV. No fee for registration.
Notification process	Notified about jobs that match education, experience, occupational preferences. Sent by text message.	Notified about jobs that match preferred job title and location. Sent by email or in the app.	Notified about jobs that match preferred experience, salary, location and optional keywords. Sent by email.	Notified about jobs that match preferred job title, salary, location and work schedule. Sent by email or in the app.
Job application process	Phone platform and ask them to send your template CV to the jobs you're interested in. No fee to apply.	If the job allows applications via LinkedIn: submit contact information, upload CV, and for some jobs answer additional job-specific questions. Otherwise redirected to the company website. No fee to apply.	If the job allows applications via Rozee: confirm contact information is correct, upload CV or submit platform-generated CV, and for some jobs answer additional job-specific questions. Otherwise redirected to the company website. No fee to apply.	Confirm contact information is correct, upload CV or submit platform-generated CV, and for some jobs answer additional job-specific questions. No fee to apply.
Other platform notes		Largest online professional networking site in the world by number of users	Largest online job search platform in Pakistan by number of users	Largest employment website in the world by number of visitors.

Notes: This table compares the processes on Job Talash for registering, being notified about matched jobs, and applying for jobs to three other prominent job search platforms. This shows substantial overlap in the processes for learning about matched jobs and submitting applications to these jobs. The other three platforms also include search functions that allow users to learn about jobs outside the match notification system.

Table A.3: Job Application Rates on Search and Matching Platforms

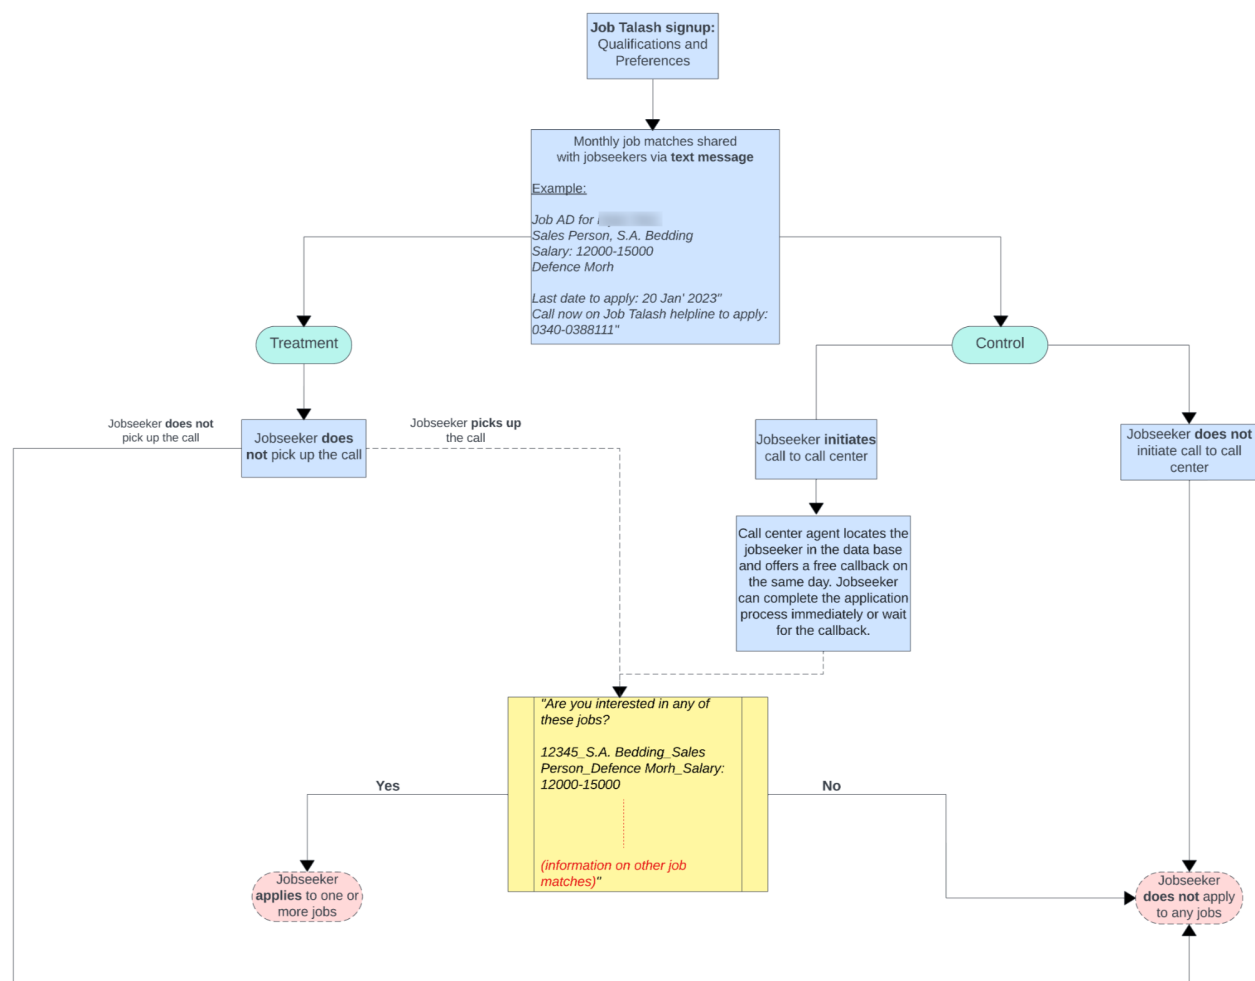

Study	Country	Platform	Mean apps per user per month	Notes
Behaghel et al. (2023)	France	La Bonne Boîte	0.02	
Martins (2017)	Mozambique	emprego.co.mz	0.03	
Wheeler et al. (2022)	South Africa	LinkedIn	0.03	
This paper	Pakistan	Job Talash	0.03	74% of users do not submit any applications.
Archibong et al. (2022)	Nigeria	Not stated	0.12	
Ben Dhia et al. (2022)	France	Bob Emploi	0.16	
Banfi et al. (2022)	United States	careerbuilder.com	0.18	
Gee (2019)	Multiple countries	LinkedIn	0.19	
Marinescu & Skandalis (2021)	France	Not stated	0.30	69% of users do not submit any applications.
Banfi et al. (2019)	Chile	trabajando.com	1.22	
Kelley et al. (2021)	India	Shikari	1.25	
Matsuda et al. (2019)	Pakistan	Rozee	3.33	Sample excludes users who submitted 0 applications.
Kudlyak et al. (2013)	United States	SnagAJob	3.60	Sample excludes users who submitted 0 applications.
Belot et al. (2018)	Scotland	Not stated	4.40	People in the sample were paid to use the platform.
Faberman & Kudlyak (2019)	United States	SnagAJob	7.64	Sample excludes users who submitted 0 applications.
He et al. (2023)	China	Not stated	28.8	Sample excludes $\approx 99\%$ of users because they are “inactive.”

This table shows job application rates for users of job search and matching platforms in published and working papers. All application rates are converted into monthly, although different papers use periods ranging from 4 weeks to multiple years. The final column notes that some papers exclude users who submit zero applications during the period of study from their sample. Some other papers restrict their sample to ‘active’ or ‘recently active’ users but do not define what this means.

Figure A.2: Sample Text Message in English (Actual Messages are Sent in Urdu)

Figure A.3: Information Structure for Phone Call Treatment and Control Jobseekers

Notes: This flowchart shows the structure of how information flows for the phone call treatment and control jobseekers. The only difference between the two is that the former receives a phone call from the platform, whereas the latter initiates the call to the platform. The content in the text message and the phone call scripts are identical for both groups.

B Additional Analysis on Search Effort and Returns to Search

B.1 Average & Heterogeneous Effects on Interview- and Application-Related Outcomes

Figure B.1 shows treatment effects on the number of times each jobseeker applies to and is invited to an interview for a job. This figure shows that treatment raises the probability of submitting K applications and getting L interviews for all K and for $L \leq 4$.

Table B.1 shows heterogeneous treatment effects by baseline employment, search status, education, and age. Treatment substantially increases both applications and interviews for all eight subgroups (panels A and B). The marginal return to additional applications ranges from 4.9 to 7.3% across the subgroups (panel C). We fail to reject constant returns to marginal search for any of the subgroups after adjusting for multiple hypothesis testing (sharpened $q > 0.30$).

Table B.2 shows treatment effects on interview probabilities weighted by different proxies for interview value, such as salary. This includes all components of the proxy index for interview value discussed in Section 3.2 and some combinations of proxies, e.g., commute-cost-adjusted salary in column 4 combines information from salary in column 1 and commute time in column 3. We show both intention-to-treat and two-stage least squares estimates but the latter are economically easier to interpret. We fail to reject equality of marginal and inframarginal returns for all eleven proxies. This supports the argument that returns to marginal treatment-induced search are roughly constant, by examining multiple possible measures of the value of search outcomes.

Figure B.1: Treatment Effects on Jobseeker-level Numbers of Applications and Interviews

Notes: This figure shows treatment effects on the number of job applications submitted and number of interview invitations received. All estimates are from regressions of the number of applications or interview invitations on treatment assignment and stratification block fixed effects, using jobseeker-level data and the sample of all jobseekers. Solid vertical lines show 95% confidence intervals, constructed using heteroskedasticity-robust standard errors.

Table B.1: Heterogeneous Treatment Effects

Group 1 vs. 0	Employed vs. Unemployed (1)	Searching vs. Not Searching (2)	Less vs. More than High School (3)	Less vs. More than 30 Years Old (4)

p: Effect = Mean Outcome Group = 1	0.67881	0.14752	0.02912	0.07413
p: Effect = Mean Outcome Group = 0	0.73195	0.22857	0.31470	0.48324
# matches	1,116,160	921,011	1,116,952	1,116,952
Proportion in Group = 1	0.41427	0.58115	0.46970	0.58101

Notes: Panel A shows the coefficients from regressing an indicator for job application on treatment assignment, stratification block fixed effects, an indicator for a group that varies between columns, and the interaction between the treatment assignment and the group indicator. Panel B shows the coefficient from regressing an indicator for interview invitation on the same right-hand side variables. The relevant group is: employed at baseline in column 1, searching at baseline in column 2, high school or higher education at baseline in column 3 (the sample median level of education), and age under 30 years old at baseline in column 4. The unit of observation is the jobseeker $\times$ vacancy match. The sample in each of the columns varies due to item non-response in the baseline survey. Heteroskedasticity-robust standard errors are shown in parentheses, clustering by jobseeker.

Table B.2: Treatment Effects on Attributes of Marginal Interviews

	ln(Salary)	High salary	ln(Salary net commute cost)	Short commute	ln(Hourly salary)	Interview × Short hours	Flexible hours	Any benefits	Exact Match Ed.	Exact Match Exp.	Gender pref. aligned

Notes: Each column in panel A shows the coefficient from regressing an indicator for interview invitation weighted by a proxy of job quality on treatment assignment. Each column in panel B shows the coefficient from regressing an indicator for interview invitation weighted by a proxy of job quality on an indicator for application, instrumented by treatment assignment. All regressions include stratification block fixed effects. The unit of observation is the jobseeker × vacancy match. The sample is all matches. Heteroskedasticity-robust standard errors are shown in parentheses, clustering by jobseeker. Mean outcomes are for the control group. The proxies for job quality used in columns (1) to (11) are ln(posted salary), a binary variable indicating the expected salary being less than 90th percentile of salaries the jobseeker is matched to on the platform, ln(posted salary net of commute cost), a binary variable indicating a short commute (less than median distance), ln(hourly posted salary), a binary variable indicating less than median working hours, a binary variable indicating whether the firm ever allows employees in this position to work flexible hours, a binary variable indicating any benefits offered by the vacancy, a binary variable indicating whether the jobseeker has an exact match of educational specialization for the job advert, a binary variable indicating whether the jobseeker has an exact match of work experience for the job, and a binary variable indicating whether the job advert states preferring candidates from the jobseeker's gender.

B.2 Robustness Checks

Table B.3 shows that our main findings from Table 3 are robust to alternative sets of conditioning variables, weighting, and clustering. Column 1 shows results from our preferred specification; column 2 includes interactions between treatment and the fixed effects, following the recommendation by [Imbens & Rubin \(2015\)](#); column 3 drops stratification block fixed effects. Results are similar across the three specifications: the effect on applications ranges from 1.28 to 1.34 percentage points and the marginal applications have a mean interview probability between 5 and 5.9%. We also show results conditioning on jobseeker-level covariates in column 4, vacancy- and match-level covariates in column 5, and all three sets of covariates in column 6. All covariates are selected using a post-double selection LASSO, following [Belloni et al. \(2014\)](#). The effect on applications ranges from 1.33 to 1.34 percentage points and the marginal applications have a mean interview probability between 5.9 and 6.9%. The findings in columns 4, 5, and 6 reinforce our argument in Section 4.4 that the main findings are not driven by treatment effects on which jobseekers use the platform or where they direct applications.

Our main analysis uses one observation per match. This gives higher weight to jobseekers who get more matches, due to their occupational preferences, educational qualifications, or work experience. We repeat our main analysis weighting the data by the inverse number of matches received by each jobseeker, which assigns equal weight to each jobseeker and makes it easier to compare results to jobseeker-level analysis using survey data. Column (7) shows that the weighted treatment effect on applications is slightly higher (1.83 percentage points), which means that jobseekers who receive fewer matches are more responsive to treatment. The weighted treatment effect on interviews increases by a slightly smaller margin, leading to a 4.6% probability of converting marginal applications into interviews. This is slightly lower than the unweighted result but is not statistically significantly different to the unweighted result or the interview probability for control group applications, with or without weights.

Our main findings are also robust to two alternative ways of estimating the standard errors: clustering by enumeration areas used for household listing (column 8) and clustering by both jobseeker and vacancy (column 9). The former approach follows a recommendation from [Abadie et al. \(2017\)](#) and is appropriate for conducting inference about all enumeration areas around Lahore, not only the enumeration areas we randomly chose for our sample. The latter approach is arguably conservative, because treatment is randomized within vacancy, but it allows for the fact that applications are correlated with vacancies across jobseekers.

Table B.3: Robustness of Main Results to Alternative Controls, Weighting, and Clustering

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)

Notes: This table shows treatment effects on key outcomes using different regression specifications. Column 1 shows results for the default sample and regression specification, which includes stratification block fixed effects and either treatment assignment (Panels A-B) or application instrumented by treatment assignment (Panel C). Column 2 includes interactions between treatment and the fixed effects (and instrument in panel C) and estimates the treatment effect as the average of the treatment * fixed effect interactions weighted by the relative sizes of the stratification blocks (following [Imbens & Rubin 2015](#)). Column 3 excludes stratification block fixed effects. Column 4, 5 and 6 include respectively, jobseeker-level controls; advert- and match-level controls; and jobseeker-, advert-, and match-level controls. The controls are selected using a post-double-selection LASSO (following [Belloni et al. 2014](#)). The LASSO model is allowed to select from the following characteristics: at the jobseeker level, age of the jobseeker, gender of the jobseeker, whether the jobseeker is married at baseline, whether the jobseeker is married and has kids at baseline, whether the jobseeker has above-median education, whether the jobseeker has any work experience at baseline, jobseeker's years of work experience, and whether the jobseeker selects many occupational categories at baseline; at the match and vacancy level, high salary relative to respondent's matches, high salary relative to all matches, high number of years of experience required relative to all matches, and jobseeker has an exact match of work experience for the job. Column 7 weights observations by the jobseeker-level inverse number of matches so each jobseeker receives the same weight. Column 8 uses the same specification used in Column 1. Heteroskedasticity-robust standard errors shown in parentheses. Column 1 - 7 include standard errors clustered by jobseeker. Column 8 includes standard errors clustered by the enumeration area of the jobseeker. Column 9 includes standard errors two-way clustered by jobseeker and vacancy. Sample sizes vary slightly across columns due to non-response affecting covariates. All units of observation are at the jobseeker $\times$ vacancy match.

B.3 Addressing Possible Violations of the IV Monotonicity Assumption

Researchers using instrumental variables to study treatment effects commonly make a monotonicity assumption. In our context, this monotonicity assumption is that the phone call treatment weakly increases the probability of application in all matches. Under this assumption all matches are either compliers, which lead to applications if and only if they are treated; always-takers, which lead to applications irrespective of treatment status; or never-takers, which do not lead to applications irrespective of treatment status. Under this assumption no matches are defiers, matches that lead to applications if and only if they are *not* treated. Note that these types are defined at the match level: the same jobseeker may be a complier in some matches, always-taker in some matches, and a never-taker in other matches.

This monotonicity assumption allows us to interpret our two-stage least squares estimate as the average treatment effect of applications on interview invitations for compliers, typically called the local average treatment effect (LATE).

If there are some defiers, two-stage least squares does not recover a well-defined treatment effect. The coefficient in a two-stage least squares regression with one binary instrument and one binary endogenous variable recovers the difference between the treatment effect on compliers and the treatment effect on defiers, weighted by their shares in the population. Define P_j as the population share of type j and ΔI_j as the treatment effect on interviews for type j . We use bold text to show that these quantities are unknown and follow this convention throughout the argument. Using this notation:

$$\beta_{2SLS} = \frac{P_C \cdot \Delta I_C - P_D \cdot \Delta I_D}{P_C - P_D}. \quad (1)$$

If the share of defiers is zero, as assumed in most empirical papers, then $\beta_{2SLS} = \Delta I_C$.

If the share of defiers is not zero, we can bound the treatment effect on compliers ΔI_C using a six-step argument that we adapt from [De Chaisemartin \(2017\)](#) and [Zhu \(2021\)](#). First, we note that the treatment effect on interviews for defiers, ΔI_D , is defined as $\mathbb{E}[I|T = 1, \text{Defier}] - \mathbb{E}[I|T = 0, \text{Defier}]$. The first term is zero because treated defiers, by definition, do not send applications and hence cannot get interviews. The second term is the mean interview rate for applications from untreated defiers, which we denote by $\bar{I}_D$. Hence we can rewrite equation (1) as

$$\Delta I_C = \frac{\beta_{2SLS} \cdot (P_C - P_D) + P_D \cdot \Delta I_D}{P_C} = \frac{\beta_{2SLS} \cdot \beta_{S1} - P_D \cdot \bar{I}_D}{\beta_{S1} + P_D}, \quad (2)$$

where $\beta_{S1} = P_C - P_D$ is the coefficient from a first stage regression of application on treatment.

Second, we note that all unknown quantities in equation (2) can be bounded. Control group matches yield applications if and only if those matches are defiers or always-takers. Hence the mean application rate in the control group, which we denote by $\bar{A}_0$, equals $P_D + P_A$. This yields

the inequality restriction

$$0 \leq \mathbf{P}_D \leq \bar{A}_0. \quad (3)$$

$\bar{\mathbf{I}}_D$ is the mean value of a binary variable. The same is true of $\bar{\mathbf{I}}_A$, the mean interview rate for applications from always-takers. Hence

$$0 \leq \bar{\mathbf{I}}_A \leq 1 \quad (4)$$

$$0 \leq \bar{\mathbf{I}}_D \leq 1. \quad (5)$$

Evaluating equation (2) in light of these three inequalities show that $\Delta \mathbf{I}_C \leq \beta_{2SLs}$, with equality when $\mathbf{P}_D = 0$, i.e. two-stage least squares recovers LATE when there are no defiers. This gives us an upper bound on $\Delta \mathbf{I}_C$. To derive the lower bound, we proceed to the next steps.

Third, we note again that any application in the control group must come from an always-taker or a defier. Hence the mean interview rate for applications submitted from control group matches, which we denote by $\bar{I}_0$, is the average of rates for always-takers and defiers weighted by their relative population shares: $(\bar{\mathbf{I}}_A \cdot \mathbf{P}_A + \bar{\mathbf{I}}_D \cdot \mathbf{P}_D) / (\mathbf{P}_A + \mathbf{P}_D)$. Recalling that $\mathbf{P}_D + \mathbf{P}_A = \bar{A}_0$ and rearranging terms gives

$$\mathbf{P}_D \cdot (\bar{\mathbf{I}}_D - \bar{\mathbf{I}}_A) = \bar{A}_0 \cdot (\bar{I}_0 - \bar{\mathbf{I}}_A). \quad (6)$$

Combining (2), (3), (4), (5), and (6) gives a system of two equality restrictions and three inequality restrictions in which $\Delta \mathbf{I}_C$ depends on three unknown quantities: $\bar{\mathbf{I}}_D$, $\bar{\mathbf{I}}_A$, and $\mathbf{P}_D$. This does not allow us to point identify $\Delta \mathbf{I}_C$ but allows us to obtain a lower bound.

Fourth, we consider each value $\mathbf{P}_D$ satisfying (3), solve for the set of values of $\bar{\mathbf{I}}_D$ and $\bar{\mathbf{I}}_A$ consistent with all the restrictions, and then solve for the set of values of $\Delta \mathbf{I}_C$ consistent with all the restrictions. Let $\{\Delta \mathbf{I}_C\}_{\mathbf{P}_D}$ denote this set of feasible values.

Figure B.2 shows, for each possible value of the share of defiers $\mathbf{P}_D$, the set of feasible values of $\bar{\mathbf{I}}_D$ in solid blue. When the share of defiers is small, only condition (4) binds on $\bar{\mathbf{I}}_D$. As the share of defiers increases, the maximum feasible value of $\bar{\mathbf{I}}_D$ shrinks to stop the left-hand side of equation (6) from becoming so large that it can only be satisfied by a value of $\bar{\mathbf{I}}_A$ that violates condition (5). As the share of defiers approaches $\bar{A}_0$ and hence the share of always-takers approaches zero, $\bar{\mathbf{I}}_D$ must approach $\bar{I}_0$ and the feasible set approaches a point.

Fifth, we construct the union of feasible sets $\{\Delta \mathbf{I}_C\}_{\mathbf{P}_D}$ over all values of $\mathbf{P}_D$, which we define as $\{\Delta \mathbf{I}_C\}$. The maximum value of $\Delta \mathbf{I}_C$ in this set occurs when $\mathbf{P}_D = 0$ and is simply β_{2SLs} . This matches the intuitive interpretation of equation (1): if there are no defiers, then the monotonicity assumption automatically holds, and hence two-stage least squares recovers the treatment effect on interviews for defiers. The minimum value of $\Delta \mathbf{I}_C$ occurs as $\mathbf{P}_D$ approaches its maximum value of $\bar{A}_0$, i.e. when there are no always-takers and all control group applications come from defiers, and hence $\Delta \mathbf{I}_D$ approaches $\bar{I}_0$. Note that $\Delta \mathbf{I}_C$ is undefined at $\mathbf{P}_D = \bar{A}_0$ because there are no compliers at that point. So the lower bound is defined by the limit as $\mathbf{P}_D$ approaches $\bar{A}_0$.

Using the estimated values of $\bar{A}_0 = 0.00185$, $\beta_{S1} = 0.01322$, $\bar{I}_0 = 0.06381$, and $\beta_{2SLs} =$

Figure B.2: Bounding the Local Average Treatment Effect Without Monotonicity

Notes: The blue solid line covers the values of the share of defiers P_D and the interview rate for applications sent by defiers I_D that are feasible, given the data-based restrictions derived in this section.

0.5852 from Table 3 yields a lower-bound estimate of 0.04352 for the average treatment effect on compliers. The bounded set for $\Delta \mathbf{I}_C$ thus equals [0.0435, 0.0585], with a width of only 1.50 percentage points.

B.4 Addressing Possible Complications around the IV Exclusion Assumption

In our application, the exclusion assumption is that treatment assignment affects interview invitations only through job applications. This is mechanically true, in the sense that interviews are only possible through job applications. Here we address three possibilities that might complicate interpretation of this assumption, without necessarily violating it. Our findings are robust to accounting for each of the three possibilities.

Treatment effects on matches received: Participants receive matches based on their education, work experience, and occupational preferences. Roughly 11% of control group respondents change job preferences after sign-up and treatment decreases this by 1.9 percentage points (Table B.4, column 2). Treatment has small effects that are not statistically significant on the probabilities of adding educational qualifications or work experience to the CV (Table B.4, columns 4-5).

These changes might in principle lead to treatment effects on the set of matches received by participants, leading to treatment-control differences in the samples used for analysis. We test whether our results are sensitive to this concern by constructing the set of matches that each respondent would have obtained if they had retained their original job preferences; we code applications and interviews as zeros for the counterfactual subset of these matches respondents did not actually receive, and estimate treatment effects in this sample. We do the same exercise with the original education and work experience information. The treatment effects on both applications and interviews are mechanically lower in these hypothetical samples. The returns to marginal and inframarginal applications range from 6.4 to 6.5% across all of these counterfactual samples, again showing roughly constant returns to marginal search effort (Table B.5, Panel C, columns 2-4).

Treatment effects on application content: Treatment might shift the content of job applications as well as the quantity of job applications. This is a standard concern with research designs based on instruments that shift quantities. For example, instruments that shift the cost of education

Table B.4: Treatment Effects on Non-Application Measures of Platform Use

	(1) # pref. updates	(2) Any pref. update	(3) Completed CV	(4) Added educ.	(5) Added work exp.
Phone call treatment	-0.07087 (0.04183)	-0.01919 (0.00663)	0.02494 (0.00896)	0.02058 (0.00496)	-0.00510 (0.00370)
# jobseekers	9,823	9,823	9,823	9,823	9,823
Mean outcome T = 0	0.56337	0.10633	0.15343	0.03558	0.02911

Notes: This table shows treatment effects on measures of platform use other than job applications: number of updated occupation preferences (column 1), an indicator for updating any occupation preference (column 2), completing their on-platform CV (column 3), adding more education information to their CV (column 4), or adding more work experience to their CV (column 5). Each column shows the coefficient from regressing the relevant outcome on treatment assignment, stratification block fixed effects, and fixed effects for the timing of the jobseeker follow-up surveys used to collect CV-related information. The unit of observation is the jobseeker. The sample is all jobseekers. Heteroskedasticity-robust standard errors are shown in parentheses.

Table B.5: Sensitivity of Treatment Effects to Accounting for Changes in Jobseeker Profile and Preferences on Platform

Panel A - Treatment effects on applications						
	Apply					
	(1)	(2)	(3)	(4)	(5)	(6)

Sample	Full sample	Hypothetical matches w/initial preferences	Hypothetical matches w/initial edu & exp	Hypothetical matches w/initial preferences & edu & exp	Completed CV at baseline	Excluding matches during stops

Notes: This table shows how treatment effects change (a) when we repeat our main analyses holding fixed jobseekers' initial occupational preferences, education, and experience so jobseekers' updates to these measures cannot influence the matches they receive, and (b) when dropping matches during periods in which the jobseeker requested a stop. Column 1 uses the sample of actual matches jobseekers receive, replicating the results in Table 3. Column 2 uses the sample of matches that jobseekers would have received if they did not update their occupational preferences. Column 3 uses the sample of matches that jobseekers would have received if they did not update their education or work experience. Column 4 uses the sample of matches that jobseekers would have received if they did not update occupational preferences, education, or experience. For all matches in columns 2, 3, and 4 that jobseekers did not actually receive, both application and interview are coded as zeros. Column 5 uses the sample of matches of jobseekers who completed their CVs at baseline. Column 6 uses the sample of matches during periods in which the jobseeker did not request to pause/stop getting matches.

Panels A and B show the coefficients from regressing respectively invitations an indicator for job application and an indicator for interview invitation on treatment assignment. Panel C shows the coefficient from regressing an indicator for interview invitation on job application, instrumented by treatment assignment. The sample size for columns 1-4 in this table is slightly smaller than in the main treatment effects table due to some missing values for preference, education or experience data. All regressions include stratification block fixed effects. The unit of observation is the jobseeker $\times$ vacancy. Heteroskedasticity-robust standard errors are shown in parentheses, clustered by jobseeker.

may shift both the quantity and quality of education attained, complicating interpretation of any ‘return to education’ estimated in these designs (Card, 2001).

However, as discussed in Section 2, our platform allows us to observe everything that the firm observes about the jobseeker and that the jobseeker observes about the firm prior to the interview invitation. Jobseekers do not receive contact information for firms before firms reach out to invite them to an interview, so it is unlikely that jobseekers could send additional information to firms.

Thus we can test directly for quality effects. The most obvious proxy for quality is CV completion, as firms are less likely to view CVs with missing fields positively. Treated candidates are 2.5 percentage points more likely than control candidates to complete missing fields on their on-platform CV after registering, mainly due to adding educational information rather than adding work experience (Table B.4, column 3). But replicating our main analysis for respondents who completed their entire CV at registration replicates our main findings (Table B.5, column 5). Treatment effects on both applications and interviews and the return to education are all slightly higher in this sample. But the returns to marginal and inframarginal applications remain very similar to each other, respectively 7.4 and 7.8%.

Treatment effects on platform engagement: Respondents can ask to stop being sent matches temporarily or permanently. Treatment increases the probability of requesting a pause or stop by roughly 12 percentage points. This is partly because treatment shifts people from passive disengagement (ignoring text messages) to active disengagement (asking to stop calls and text messages). Our main analysis retains matches from jobseekers who request stops, and codes applications and interviews for these matches as zeros. As a sensitivity check, we can instead drop observations from jobseekers during periods when they have requested stops. This mechanically slightly increases treatment effects on applications and interviews (Table B.5, column 6). But the returns to marginal and inframarginal applications are respectively 5.9% and 6.4% in this sample, almost identical to the full sample.

Alternative approach to testing constant returns to search: We show evidence consistent with constant returns to search using an alternative method that makes slightly different assumptions to the instrumental variables method in the main paper. This method is adapted from Attanasio et al. (2011) and Carranza et al. (2021). We first estimate the treatment effect on the application probability multiplied by the control group’s mean interview:application ratio, which we call the *CR-implied effect*. This quantity captures the increase in job interviews that would occur if treatment shifted interviews only by shifting the quantity of job applications, but had no effect on the probability of converting job applications into interviews. Under constant returns, the CR-implied effect should equal the average effect of treatment on the interview probability, a hypothesis we can test directly.

The CR-implied effect and average effect of treatment on interviews are very similar. Multiply-

ing the 1.322 percentage point effect on application probability and the 0.0638 ratio of interviews to applications in the control group yields a CR-implied effect of 0.084 p.p., with standard error 0.05 p.p. (Table B.6, column 1, row 2). This is almost identical to the treatment effect on interviews of 0.077 p.p (column 1, row 1). The 0.007 p.p. difference between them is both small and not significantly different to zero, with standard error 0.007 p.p. (column 1, row 3). The CR-implied effect and average effect of treatment on ‘value-weighted’ interviews are also similar. Recall that our main measure of value-weighted interviews from Section 3 is the interview indicator multiplied by an inverse covariance-weighted average of the eight proxies for the value of the interview. For this measure, the CR-implied effect and average effect differ by only 0.0004 with standard error 0.0003, roughly 10% of the average effect (Table B.6, column 2, row 3).

Table B.6: Alternative Test for Constant Returns to Search

	(1) Interview	(2) Interview $\times$ V_{vm} index
Treatment effect	0.00077 (0.00009)	0.00283 (0.00036)
Constant-returns implied effect	0.00084 (0.00005)	0.00324 (0.00018)
Difference	-0.00007 (0.00007)	-0.00041 (0.00028)
# matches	1,116,952	1,116,952
# jobseekers	9831	9831
Mean outcome T = 0, Apply = 1	0.06381	0.24487

This table compares treatment effects on interviews (row 1) to the treatment effects on applications multiplied by the mean interview:application ratio in the control group (row 2). Under constant returns, these two quantities will be identical. Hence we name the effect in row 2 the ‘CR-implied effect.’ Each column shows results for a different outcome: interviews in column 1 and interviews multiplied by an inverse covariance-weighted average of eleven proxies for the value of an interview in column 2. The proxies are defined in the note to Table 3. The unit of observation is the jobseeker $\times$ vacancy match. The sample is all matches. All regressions include stratification block fixed effects. Heteroskedasticity-robust standard errors are shown in parentheses, clustering by jobseeker.

B.5 Treatment Effects on Employment and Off-Platform Search

Tables B.7 and B.8 show treatment effects on employment and off-platform search, reported in a survey of jobseekers. They show that the effect on employment is positive and effects on search measures are negative, but all of these are small and not statistically significant.

Appendix B.6 explains how we construct the selection correction terms shown in even-numbered columns of these tables.

Table B.7: Treatments Effects on Off-Platform Search and Work

	Any Off- Platform Search		Any Work	
	(1)	(2)	(3)	(4)
Phone call treatment	-0.00826 (0.01630)	-0.01026 (0.02080)	0.00130 (0.01587)	0.01065 (0.02003)
# jobseekers	4327	9823	4643	9823
# jobseekers answered T = 0	2445	2445	2587	2587
# jobseekers answered T = 1	1882	1882	2056	2056
Mean outcome T = 0	0.26748	0.26748	0.73405	0.73405
Adjusted for non-response	No	Yes	No	Yes
IV strength test: F-stat		170.381		132.783
IV strength test: p-value		0.000		0.000

Notes: This table shows treatment effects on off-platform search and work. The outcome in columns (1) and (2) is an indicator for whether the jobseeker reported searching for work in the last 14 or 30 days, excluding job applications through the Job Talash platform. The outcome in columns (3) and (4) is an indicator for whether the jobseeker reported working in the last 14 or 30 days. Recall periods of 14 or 30 days are randomly assigned. Each outcome is regressed on an indicator for treatment assignment and stratification block fixed effects. Columns (2) and (4) include selection adjustment terms for survey non-response described in Appendix B.6 and using the method proposed by DiNardo et al. (2021). They use as instruments random assignment to receiving two additional call attempts, a heads-up text message before the call, a monetary incentive for answering the call and finishing the survey, and early call attempts. The unit of observation is the jobseeker. The IV strength tests are for joint tests that all the instruments have zero coefficients in the first stage. All specifications include stratification block fixed effects. Standard errors shown in parentheses. For columns without non-response adjustments, these are heteroskedasticity-robust. For columns with non-response adjustments, these are estimated using 500 iterations of a nonparametric bootstrap.

Table B.8: Treatment Effects on Off-Platform Search (Intensive Margin)

	Off- Platform Applications		% Search Methods Used	
	(1)	(2)	(3)	(4)
Phone call treatment	-0.18882 (0.14812)	-0.21265 (0.18591)	-0.01300 (0.01082)	-0.01031 (0.01390)
# jobseekers	2715	9823	1646	9644
# jobseekers responded T = 0	1565	1565	951	951
# jobseekers responded T = 1	1150	1150	695	695
Mean outcome T = 0	1.24281	1.24281	0.09976	0.09976
Adjusted for non-response	No	Yes	No	Yes
IV strength test: F-stat		146.121		65.303
IV strength test: p-value		0.000		0.000

Notes: This table shows treatment effects on specific off-platform search behaviors. The outcome in columns (1) and (2) is the number of applications submitted off-platform in the last 30 days and in columns (3) and (4) is the share of the following 7 search methods the respondent reported using: searching for clients, preparing CV or other related documents, seeking assistance from friends or relatives, visiting employers, searching in newspaper/-magazine/social media, contacting some organization, and other steps. Each outcome is regressed on an indicator for treatment assignment and stratification block fixed effects. Odd-numbered columns include selection adjustment terms for survey non-response as described in Section B.6, following DiNardo et al. (2021). The unit of observation is the jobseeker. The first-stage F-statistics jointly test the strength of the four excluded instruments. Standard errors shown in parentheses. For columns without non-response adjustments, these are heteroskedasticity-robust. For columns with non-response adjustments, these are estimated using 500 iterations of a nonparametric bootstrap. Sample size varies across columns because we randomly rotated which questions about intensive margin search were included in each survey.

B.6 Adjusting for Selection into Survey Response

We survey jobseekers about their off-platform search, employment, and beliefs about the platform and use this in parts of our analysis. The survey response rates are 53.3 and 42.7% for jobseekers in respectively the phone call control and treatment groups. This means that the treated and control group *survey respondents* might be systematically different, even though randomization ensures no systematic differences between the treated and control group *jobseekers*. However, reassuringly, survey responders and non-responders have almost identical job application rates (Table B.9).

In the presence of survey non-response, average treatment effects on outcomes are not identified without further assumptions. We use a selection adjustment method proposed by DiNardo et al. (2021) that permits identification under weaker assumptions than most other methods. To implement this method, we deliberately randomize features of the survey data collection: the order in which respondents are called, the number of call attempts made to each respondent, whether respondents get text message alerts before phone calls, and whether respondents are offered financial incentives. This allows us to use a selection correction in the spirit of Heckman (1974): we regress off-platform search or employment on treatment and a selection correction term, estimated from a first stage regression of survey response on treatment and the randomised survey features.

DiNardo et al. (2021) show that this approach recovers the population average treatment effect under four assumptions: the survey features are randomized, the survey features do not directly influence outcomes, the survey features influence the probability of response, and the error distribution for the outcome and selection models are jointly normally distributed. The first assumption holds by design. The second assumption is only violated if people are more likely to misreport under some survey features than others, which we view as unlikely but is not testable. The third assumption is testable and holds, as we show below. The fourth assumption is, like all distributional assumptions, arbitrary. But if it fails, this approach still recovers an average treatment effect for the subset of respondents who switch their survey response status in response to variation in the instruments (analogous to compliers in a LATE analysis).

We show the first-stage relationship between the randomized survey features and the response rate for each type of survey question in Table B.10. There are four types of survey questions: any off-platform work, any off-platform search, the proportion of specific search activities done, and beliefs about jobs on the platform. The instruments have a strong impact on the probability of response for all four types of survey questions, shown in the columns. Extra call attempts are the most important instrument, raising the probability of response by 6-11 percentage points with standard errors below 1 p.p. for each four question types. We can strongly reject the null hypothesis that their coefficients are jointly zero ($p < 0.001$ and $F \in [79, 150]$ across the four models).¹

¹The common rules-of-thumb for instrument strength, e.g. $F > 10$, are not directly applicable here. They are designed for two-stage least squares estimation rather than the control function estimation we use. Nonetheless,

Table B.9: Comparing Platform Use for Survey Respondents and Non-Respondents

	(1) Ever applied	(2) Ever invited	(3) # applications	(4) # interviews
Ever answered survey	-0.00514 (0.00917)	0.00950 (0.00407)	0.02509 (0.06718)	0.01523 (0.00754)
# jobseekers	9824	9824	9824	9824
Mean outcome Never answered survey	0.26309	0.03335	0.91574	0.04753
Prop. ever answered survey	0.36818	0.36818	0.36818	0.36818

Notes: This table tests whether survey response is related to different dimensions of platform use as measured by administrative data. Ever answered survey is defined as a dummy equal to 1 if a jobseeker was ever successfully reached for a 20% regular or bonus call, and reached the first module of questions. The unit of observation is the jobseeker. Heteroskedasticity-robust standard errors in parentheses.

We report treatment effects both with and without adjustments for survey responses for all analyses based on survey responses: any off-platform search or employment (Table B.7), specific off-platform search activities (Table B.8), receipt of calls/text messages (Table C.15), and beliefs about jobs on the platform (Table C.16). Adjusting for selection generally makes little difference.

Many researchers instead focus on bounding a different parameter: the average treatment effect in the subpopulation that responds irrespective of treatment status, following Lee (2009). This approach does not require instruments but the bounds are too wide in our setting to be informative.

We can implement a nonparametric version of the DiNardo et al. (2021) method that has a similar spirit to Lee bounds. In this implementation, we split jobseekers into cells based on the combination of randomized survey features they are assigned (e.g. extra call attempts, early call, no survey incentive, no text message in advance). We then select ‘response-balanced cells’: cells where response rates are balanced between treatment and control groups. Using only the response-balanced cells allows unbiased estimation of average treatment effects for the subpopulation of jobseekers who respond to the survey when they are assigned these specific combinations of survey responses. Intuitively, this approach uses the instruments to identify subpopulations where response rates are balanced between treatment and control groups, collapsing the Lee-style bounds to a single point. This has a similar approach to Lee’s suggestion to use covariates to tighten bounds, with the added advantage that we use randomized instruments rather than non-random covariates. Using this approach yields similar point estimates to the main parametric analysis. But using only the response-balanced cells leads to larger standard errors, so we do not emphasize these results.

the statistically strong relationship between response and the instruments is reassuring. As an alternative metric for evaluating instrument strength, following Garlick & Hyman (2022), we note that the instruments jointly shift the probability of responding by at least 9 percentage points in each of the four models. For example, a jobseeker is 12.8 percentage points more likely to complete the beliefs module if she gets extra call attempts, no pre-call text message alerts, and no financial incentive than if she gets a pre-call text message alert, a financial incentive, and no extra call attempts.

Table B.10: Effect of Randomized Survey Features on Probability of Answering Survey Modules

	Respondent answered survey module on:			
	Beliefs	Search	Work	Intensive-Margin Search
	(1)	(2)	(3)	(4)
Many call attempts	0.09597 (0.00805)	0.10968 (0.00969)	0.10369 (0.00977)	0.06479 (0.00747)
Text message before call	0.00918 (0.01342)	0.01204 (0.01640)	0.01894 (0.01650)	0.00288 (0.01237)
Incentive	-0.00179 (0.01339)	-0.02066 (0.01628)	-0.02746 (0.01636)	-0.00672 (0.01229)
Text message before call $\times$ Incentive	-0.03933 (0.02246)	-0.04929 (0.02723)	-0.03915 (0.02734)	-0.01974 (0.02068)
Assigned early call		-0.00926 (0.02051)	-0.01824 (0.02063)	
# jobseekers	9824	9824	9824	9824
Mean outcome	0.21241	0.44089	0.47262	0.16791
IV strength test: F-stat	149.907	145.690	129.027	79.075
IV strength test: p-value	0.000	0.000	0.000	0.000

Notes: This table shows the effect of randomized survey features on the probability that jobseekers answer each survey module. We use these estimates to construct selection correction terms for all analyses using survey data, following [DiNardo et al. \(2021\)](#). The outcomes are indicators for ever answering: the survey module about beliefs (column 1), a binary question for any off-platform search (column 2), a binary question for any employment (column 3), and the survey module about intensive-margin off-platform search (column 4). We ask the two binary questions on every call attempt. For a subset of calls, we randomly select one of the beliefs module or the intensive-margin off-platform search module to ask. The randomized features are extra survey call attempts (row 1), a text message telling the respondent that they will be called soon (row 2), an incentive payment of 100 Pakistani Rupees for answering the call (row 3), and assignment to be called early in the survey operation (row 5). We include the interaction between the text message and survey incentive (row 4) because these are directly cross-randomized in the same set of call attempts. The early call attempts were only randomized for a subset of calls that did not include the belief or intensive-margin search questions, so we omit this feature from the regression models shown in columns (1) and (4). All regressions include a treatment indicator and stratification block fixed effects. Heteroskedasticity-robust standard errors shown shown in parentheses. The bottom two rows of the table report results for testing if the coefficients on the randomized survey features are jointly equal to zero.

C Additional Analysis on Explaining Marginal Returns to Search

C.1 Overview

This appendix provides detailed methods and results to support the argument in Section 4 of the paper – “Explaining Marginal Returns to Search.” For each of the additional experiments described in this appendix, only a very small share of the matches in the sample are treated. For our analysis of the main phone call treatment, we do not take these treatment assignments into account. Table C.1 shows that including indicators for each different treatment in our main regressions has almost no impact on the estimated effects of the main phone call treatment.

To help the reader navigate this appendix, we provide three tables on the next three pages that summarize all analyses in this appendix. Table C.2 summarizes the additional tests of our conceptual framework. These tests are covered in Appendix C.4. They are based on data patterns in the control group or comparisons of the control and treatment groups from our main experiment. Table C.3 summarizes all additional experiments and additional analyses we use to understand the nature of application costs (e.g. pecuniary, time, psychological). This content is covered in detail in Appendix C.5. Table C.4 summarizes the evidence we use to evaluate alternative explanations. This evidence is covered in detail in Appendix C.6. Each table lists the research question, method, finding, corresponding appendix section/table/figure containing more details, numbers of jobseekers and matches involved, and - for the additional experiments only – the unit of randomization (jobseeker, jobseeker $\times$ round, or jobseeker $\times$ vacancy) and share of units randomized.

Table C.1: Treatment Effects on Job Search & Search Returns, Controlling for All Other Treatments

	(1) Apply	(2) Interview	(3) Int. $\times V_{vm}$	(4) Interview	(5) Int. $\times V_{vm}$
Phone call treatment	0.01338 (0.00075)	0.00078 (0.00009)	0.00285 (0.00036)		
Apply				0.05827 (0.00512)	0.21281 (0.02145)
# matches	1,116,952	1,116,952	1,116,952	1,116,952	1,116,952
# jobseekers	9831	9831	9831	9831	9831
Mean outcome T = 0	0.00185	0.00012	0.00045	0.00012	0.00045
Mean outcome T = 0, Apply = 1				0.06381	0.24487
p: IV effect = mean T = 0, Apply = 1				0.554	0.397
IV strength test: F-stat				315.6	315.6
IV strength test: p-value				0.00000	0.00000

Notes: This table shows that the estimates in Table 3 are unchanged when we include in each regression indicator variables for the random subset of control group matches that were assigned to any other treatment in a subset of rounds. All other sample definitions, regression specifications, and inference methods are identical to Table 3.

Table C.2: Additional Tests of the Conceptual Framework – Covered in Detail in Appendix C.4

Question	Method		Result & Interpretation		Appendix	
	Type	Description	# jobseekers	# matches		
All analysis in this table is based on two proxies for match value for all jobseeker $\times$ vacancy matches: salary, and the index of all positive attributes defined in Section 3.2.						
Do control group jobseekers miss applying to some high-value matches?	Additional analysis	Divide all matches into quintiles in multiple different ways: using the distribution of value proxies over all matches, using the within-jobseeker distribution of value proxies over all matches, and using the distribution of value proxies at the jobseeker $\times$ matching round level rather than match level. Calculate the share of matches in each quintile that receive applications from control and treatment group jobseekers.	9,831	1,116,952	Higher-value matches receive more applications but many high-value matches receive no applications: <0.1% of top-quintile matches receive applications from the control group and <50% of all control group applications are sent to top-quintile matches. Consistent with the conceptual framework's prediction that control group jobseekers miss applying to many high-value matches.	Appendix C.4, Figures C.2-C.6
Are treatment-induced job applications sent to matches with systematically similar attributes to matches that the control group apply to?	Additional analysis		9,831	1,116,952	The share of all treatment group applications that go to the matches in the Qth quintile of value is equal to the share of control group applications that go to the matches in the Qth quintile of value, averaged across all quintiles 1, ..., 5. Shows that treatment induces more job applications but that these are not sent to systematically higher- or lower-value matches than control group applications. Consistent with the conceptual framework's prediction that treatment-induced applications should go to matches with similar mean values to those in the control group.	Appendix C.4, Figures C.2-C.6
Are treatment-induced job applications sent to matches with systematically similar attributes to matches that the control group apply to?	Additional analysis	Calculate the means of the value proxies for matches that get applications from the treatment group. Compare these to the means for matches that get applications from the control group.	2,567	9,088	Marginal and inframarginal job applications are sent to jobs with similar means for the value proxies. Consistent with the conceptual framework's prediction that treatment-induced applications should go to matches with similar mean values to those in the control group.	Appendix C.4, Table C.5
Are treatment-induced job applications sent to matches with wider variance of attributes than matches that the control group apply to?	Additional analysis	Calculate the distributions of the value proxies for matches that get applications from the treatment group. Compare these to the distributions for matches that get applications from the control group.	2,567	9,088	The variances of the value proxies are higher in the treatment than the control group. The 10th percentiles of the value proxies are lower in the treatment than the control group. Consistent with the conceptual framework's prediction that treatment-induced applications should go to matches with more dispersed values than in the control group.	Appendix C.4, Table C.6

Table C.3: Understanding Application Costs – Covered in Detail in Appendix C.5

Question	Method						Result & Interpretation	Appendix
	Type	Description	# jobseekers	# matches	unit randomized	% units treated		
Does lowering the pecuniary cost of applying increase the application rate by as much as the main treatment?	Additional experiment	For some control group jobseekers in one round, include additional information with their usual text message list of new matches: a reminder that they can apply by sending the platform a text message to request a free callback. This avoids the pecuniary cost of initiating a phone call.	3,081	9,421	jobseeker $\times$ round	50%	This treatment has an effect on the job application rate that is one hundredth as large as the effect of the main phone call treatment. The two effects are statistically significantly different ($p = 0.017$). Implies that pecuniary costs of applying are unlikely to explain our main results.	Appendix C.5.1, Table C.7
Does lowering the time cost of applying increase the application rate by as much as the main treatment?	Additional experiment	For some control group jobseekers in some rounds, include additional information with their usual text message list of new matches: a notification that they can apply by sending the platform a text message to request a free callback at a specific time of their choice. This avoids the need to wait for their call to be answered when they call the platform and hence saves time.	3,634	29,985	jobseeker $\times$ round	33%	This treatment has an effect on the job application rate that is one quarter as large as the effect of the main phone call treatment. The two effects are statistically significantly different ($p = 0.002$). Implies that time costs of applying are unlikely to explain our main results.	Appendix C.5.1, Table C.7
Does the phone call treatment increase application rates by functioning as a reminder?	Additional experiment	For some control group jobseekers in some rounds, send a second text message reminding them about their new matches that month. This provides a reminder.	3,634	29,985	jobseeker $\times$ round	33%	This treatment has an effect on the job application rate that is one-fourteenth as large as the effect of the phone call treatment. Implies that reminder effects are unlikely to explain our main results.	Appendix C.5.2, Table C.8
	Additional experiment	Estimate how the phone call treatment effect varies with the randomized length of time between the initial text message and phone call.	6,430	530,734	jobseeker $\times$ round	NA	The phone call treatment has a smaller effect when there is more time between the text message and phone call. If phone calls worked as reminders, then their effects should be larger when this time gap is larger, because jobseekers have more time to forget to apply. Implies that the "phone calls as reminders" interpretation is relatively unlikely.	Appendix C.5.2, Table C.9
	Additional analysis	Estimate how the phone call treatment effect varies with the length of time between the initial text message and the job application deadline.	9,011	1,005,463	NA	NA	The phone call treatment has a smaller effect when there is more time between the text message and application deadline. If phone calls worked as reminders, then their effects should be larger when this time gap is larger, because jobseekers have more time to forget to apply. Implies that the "phone calls as reminders" interpretation is relatively unlikely.	Appendix C.5.2, Table C.9
	Additional analysis	Test if treatment group jobseekers are more likely to apply for the first job listed on the call and text message, which would be a way to satisfy pressure to apply as quickly as possible.	1,897	6,673	NA	NA	Treatment and control group jobseekers submit equal shares of applications to the first listed job (31%). Hence it is unlikely that treated jobseekers are applying more to simply avoid pressure to apply.	Appendix C.5.3, Figure C.7
Do phone calls pressure jobseekers to apply for jobs?	Additional analysis	Test if treatment group jobseekers who answer calls in early rounds of the experiment are less likely to answer calls in later rounds, which might happen if they want to avoid pressure during calls to apply for jobs.	3,534	13,840	NA	NA	Jobseekers who answer calls in early rounds are more likely to answer calls in later rounds, conditional on observed characteristics and using multiple different definitions of "answered" and "early". Hence it is unlikely that jobseekers actively avoid calls to avoid pressure to apply. Hence it is unlikely that treatment increases applications through pressure to apply.	Appendix C.5.3, Table C.10

Table C.4: Evaluating Alternative Mechanisms – Covered in Detail in Appendix C.6

Question	Method						Result & Interpretation	Appendix
	Type	Description	# jobseekers	# matches	unit randomized	% units treated		
Are treatment-induced job applications sent to matches with similar attributes to matches to which the control group applies?		See Table C.2 row 1 for methods used in this analysis.					Treatment and control applications are sent to jobs with similar value proxies. Hence it is unlikely that the types of jobs to which applications are sent affects the relative returns to marginal versus inframarginal applications.	Appendix C.6.1
Do treatment-induced job applications come from jobseekers with similar attributes to job applications from the control group?	Additional analysis	For each match that receives an application, calculate the characteristics of the applicant (e.g. education, work experience, CV quality, predicted interview probability) and compare these between the treatment and control groups.	2,567	9,088	NA	NA	Applications in the treatment and control groups come from observationally similar jobseekers. Hence it is unlikely that jobseeker selection into applications affects the relative returns to marginal versus inframarginal applications.	Appendix C.6.2, Table C.11
	Additional analysis	Randomly select some control group jobseekers in some matching rounds to get phone calls so we can estimate treatment effects conditional on jobseeker fixed effects. Test if the effects of this temporary treatment are equal to the permanent treatment.	3,113	14,366	jobseeker × round	50%	The temporary and permanent treatment have very similar effects on job application rates and very similar returns to marginal job applications. Hence it is unlikely that time-invariant characteristics are different for jobseekers submitting applications in the treatment and control groups.	Appendix C.6.2, Table C.12
Do phone calls provide more information about specific jobs than text messages?	Additional analysis	Restrict to the 80% of matching rounds where call centre agents had no additional information about specific jobs, so it was impossible for them to provide specific information.	9,603	801,922	NA	NA	Treatment effects are very similar in the full sample and the 80% of matching rounds where call center agents could provide no additional information. Also note that call center agents are trained to use specific scripts that give no additional information to jobseekers, and audits of calls confirm that they followed scripts. Hence it is unlikely that the phone call treatment provides additional information about specific jobs.	Appendix C.6.3, Table C.14
Are jobseekers more likely to receive phone calls than text messages?	Survey	Phone jobseekers (separately from the matching phone calls) and ask if they received a match within a specific period. Test if the probability of reporting that they received a match differs between the treatment and control groups.	1,955	NA	NA	NA	Jobseekers in the treatment and control groups are equally likely to recall receiving matches from the platform, with or without adjusting for survey non-response. Implies that the treatment effect on applications is not caused by jobseekers being more likely to receive phone calls than text messages. But survey non-response means this result is uncertain.	Appendix C.6.3, Table C.15
Does the phone call treatment change jobseekers' beliefs about the value of jobs or the probability of job offers?	Survey	Phone jobseekers (separately from the matching phone calls) and ask their beliefs about jobs on the platform: the share of jobs that are desirable for them and the share of desirable jobs that would give them a job offer if they applied. Test if their beliefs differ between the treatment and control groups.	2,003	NA	NA	NA	Treatment has near-zero impact on jobseekers' beliefs about the quality of jobs on the platform or probability of getting an offer, with or without adjusting for survey non-response. Hence it is unlikely that treatment increases job applications by changing the perceived returns to applying. But survey non-response means this result is uncertain.	Appendix C.6.4, Table C.16
	Additional experiment	Randomly select some control group jobseekers in some matching rounds to get phone calls. Test if the effects of this temporary treatment are different to the permanent treatment. The temporary treatment seems more unusual to jobseekers, so it might have larger effects on their beliefs and hence application decisions.	3,113	14,366	jobseeker × round	50%	The temporary and permanent treatment have very similar effects on job application rates and very similar returns to marginal job applications. Hence it is unlikely that phone calls shift application decisions by signaling that these are unusually high-value matches.	Appendix C.6.4, Table C.12 (also discussed in Appendix C.6.2)
Do jobseekers choose randomly where to apply, so the expected outcome of each application is equal and returns to marginal and inframarginal applications are equal?	Additional analysis	Test if matches with more desirable attributes (e.g., salary, benefits, commute distance) are more likely to get applications.	2,567	9,088	NA	NA	Jobseekers are more likely to apply to matches with more desirable attributes, in both the treatment and control groups.	Appendix C.6.5, Table C.5 (also discussed in Appendix C.4)
	Additional experiment	Randomize the order that matches are listed in text messages and phone calls. Estimate the treatment effects of being listed first.	9,255	938,284	match	100%	Jobs listed first get substantially more applications. But the marginal return to these applications is < 1/2 as large as the marginal return to applications induced by the main phone call treatment. Shows that marginal applications to random jobs have decreasing returns, which is inconsistent with random search.	Appendix C.6.5, Table C.17

C.2 Conceptual Framework Appendix

This appendix provides a more formal version of the conceptual framework from Section 4.1.

The platform sends each jobseeker a monthly batch of vacancies that match their education, experience, and occupational preferences. We define P_{jv} as the probability that jobseeker j gets an interview for vacancy v conditional on applying to the vacancy and V_{jv} as the value of an interview. V_{jv} is a reduced-form measure of the present risk-adjusted value of the flow of future utility from the interview. We define C_{jv} as the cost to jobseeker j of applying to vacancy v . We omit the jv subscript in the remainder of this section for simplicity. The expected gross return to applying is $PV\delta\beta$, where the quasi-hyperbolic discounting term $\delta\beta$ with $\delta, \beta, \leq 1$ (following Laibson 1997) reflects the fact that interviews occur after applications and allows for the possibility that jobseekers are present-biased. We make the natural assumption that jobseekers apply to all jobs where the expected net present value of applying is positive. This is assumption (A1) in the main paper text and can be written as $PV\delta\beta - C > 0$ or $PV > \frac{C}{\delta\beta}$.

We can introduce heterogeneous application costs into this framework in multiple ways. We begin by assuming that in each month share q of jobseekers face the low application cost $C\alpha < C$, while the remaining share $1 - q$ of jobseekers face the high application cost C . This mimics the dynamic investment model of Carroll et al. (2009), used to study retirement contributions. From the model's perspective, it does not matter if this cost is time-varying, with jobseekers moving between low- and high-cost status each month, or time-invariant, with some jobseekers facing permanently high costs and others facing permanently low costs.

We assume that the costs and returns are such that low-cost jobseekers apply to at least one match and high-cost jobseekers apply to no matches. This is assumption (A2) in the main paper text. Formally, this means that $PV > \frac{C\alpha}{\delta\beta}$ for some matches, so low-cost jobseekers apply to some jobs, and $PV < \frac{C}{\delta\beta}$ for all matches, so high-cost jobseekers apply to no jobs. This assumption matches the empirical patterns in the control group: some jobseekers submit applications but many jobseekers never apply or apply in only some periods. We assume costs are either high or low but all predictions of the framework hold with continuously distributed heterogeneity, provided this leads some jobseekers to apply for no vacancies in some periods.

Figure C.1 shows application behavior under these assumptions. In the top panel, low-cost jobseekers apply to the blue-shaded section of the density of PV . In the bottom panel, high-cost jobseekers apply to none of their matches. The figure shows identical densities of PV for the two types of jobseekers but the framework's qualitative predictions hold with different densities.

Treatment lowers the application cost, reducing C by a factor $\gamma \in (0, 1)$. Treated low-cost jobseekers apply if $PV > \frac{C\alpha\gamma}{\delta\beta}$. Because $\gamma < 1$, these applications must have lower expected returns than applications submitted by untreated low-cost jobseekers. These applications go to matches in the pink-shaded section in the top panel of Figure 1. Treated high-cost jobseekers apply

Figure C.1: Application Decisions for Treated & Control Jobseekers Facing High Versus Low Costs

Notes: This figure shows the application decisions for jobseekers facing low application costs at the time they receive matches (top panel) and jobseekers facing high application costs at the time they receive matches (bottom panel). The blue-shaded sections show the matches to which control group jobseekers apply. The pink-shaded sections show the additional matches to which treatment group jobseekers apply. For simplicity, we show only the right tail of the density of PV . This figure is identical to Figure 1 in the main paper, except that the horizontal axis labels show the values for the decision cutoff rules implied by the model.

if $PV > \frac{C\gamma}{\delta\beta}$, shown in the pink-shaded section in the bottom panel. If $\gamma > \alpha$, i.e., if the treatment-induced drop in application costs is small relative to the natural variation in costs, then these treated high-cost jobseekers' bar for applying is higher than $\frac{C\alpha}{\delta\beta}$, the untreated low-cost jobseekers' bar for applying. This shows the core intuition of the model: marginal applications induced by treatment come from a mix of low-cost jobseekers, whose applications have returns lower than the inframarginal applications, and high-cost jobseekers, whose applications have returns higher than the inframarginal applications if $\gamma > \alpha$. Averaged over these two types of jobseekers, marginal applications can have equal returns to inframarginal applications.²

This framework can also explain the large treatment effect on the application rate. The control group's low application rate suggests that the share q of low-cost jobseekers in each month is $\ll 0.5$. When q is low, most treatment-induced marginal applications come from high-cost jobseekers, so the treatment effect on the application rate will exceed the control group application rate.³

This setup matches some of the potential psychological costs of initiating applications that we discuss in Section 4.1. For example, jobseekers facing the low application cost $C\alpha$ might have lower costs of paying attention to text messages and evaluating the matches, perhaps because they have fewer competing demands for their attention that month.

We can adapt the model slightly to better align with other potential psychological costs of initiating applications. For example, we can adapt the model to align with varying present bias by assuming all jobseekers face application cost C but that in each month share q of jobseekers are time-consistent and have $\beta = 1$, while the remaining share $1 - q$ of jobseekers are present-biased and have $\beta < 1$. This delivers identical decision rules to those derived above with α replaced by $1/\beta$. This approach mimics the dynamic investment model that [Duflo et al. \(2011\)](#) use to study farmers' fertilizer investment. This version of the model matches the data if the share of present-biased jobseekers is high in each period, which is consistent with multiple studies finding relatively high rates of present bias, reviewed by [Kremer et al. \(2019\)](#).

² Formally, the mean average return in the control group is $\mathbb{E} \left[PV | PV > \frac{C\alpha}{\delta\beta} \right]$, while the average return in the treatment group is a weighted average of $\mathbb{E} \left[PV | PV > \frac{C\alpha\gamma}{\delta\beta} \right]$ for low-cost jobseekers and $\mathbb{E} \left[PV | PV > \frac{C\gamma}{\delta\beta} \right]$ for high-cost jobseekers. Under our assumption that $\gamma \in (\alpha, 1)$, the second and third expectations are respectively lower and higher than the mean return for control group jobseekers. The second and third expectations have weights $q \cdot Pr \left(PV > \frac{C\alpha\gamma}{\delta\beta} \right)$ and $(1 - q) \cdot Pr \left(PV > \frac{C\gamma}{\delta\beta} \right)$ respectively. If the density of PV is strictly continuous, there exists a share q of low-cost jobseekers that equalizes the average returns to control and treated applications.

³ Formally, the control group application rate is $q \cdot Pr \left(PV > \frac{C\alpha}{\delta\beta} \right)$. The treatment group application rate is $q \cdot Pr \left(PV > \frac{C\alpha\gamma}{\delta\beta} \right) + (1 - q) \cdot Pr \left(PV > \frac{C\gamma}{\delta\beta} \right)$. The first term in the treatment group application rate is already larger than the control group application rate because γ is defined to be < 1 . [Figure C.1](#) shows this. The probability in the second term in the treatment group application rate is lower than the probability in the control group application rate under our assumption that $\gamma > \alpha$. But the second term can still be substantially higher than the control group application for low values of q .

C.3 Methods for Complier / Latent Type Analysis

Several analyses we report in subsequent appendices are based on comparisons of the characteristics of marginal job applications submitted due to treatment and inframarginal job applications that would be submitted in the absence of treatment. In this appendix we describe the method used to identify the characteristics of marginal and inframarginal job applications, which is adapted from [Marbach & Hangartner \(2020\)](#).⁴

In the standard language of instrumental variable analysis, inframarginal applications are submitted by ‘always-taker’ types and marginal applications are submitted by ‘complier’ types. ‘Never-taker’ types do not submit applications by definition and there are no ‘defier’ types under the standard monotonicity assumption. *Note that type is defined at the level of the jobseeker $\times$ vacancy match.* Hence a jobseeker can submit a marginal application to one match – they would apply to that job if and only if treated – and submit an inframarginal application to another match – they would apply if assigned to treatment or control. And a vacancy can receive a marginal application from one jobseeker and an inframarginal application from another jobseeker.

We cannot observe the latent type of each individual match. But all applications submitted to untreated matches are by definition inframarginal. Hence the population share of inframarginal applications is $\mu^{AT} = \mathbb{E}[\text{Apply} \mid \text{Treat} = 0]$ and the mean value of each covariate X for inframarginal applications is $\mu_X^{AT} = \mathbb{E}[X \mid \text{Apply} = 1, \text{Treat} = 0]$.

All applications submitted to treated matches are by definition either marginal or inframarginal. The treatment group’s mean application rate is $\mathbb{E}[\text{Apply} \mid \text{Treat} = 1]$, so the population share of marginal applications is $\mu^C = \mathbb{E}[\text{Apply} \mid \text{Treat} = 1] - \mu^{AT}$. The mean value for each covariate X in the treatment group is the average of the mean values for compliers and always-takers, weighted by their relative frequency: $\mathbb{E}[X \mid \text{Apply} = 1, \text{Treat} = 1] = \frac{\mu^{AT} \cdot \mu_X^{AT} + \mu_X^C \cdot \mu^C}{\mu^{AT} + \mu^C}$. Hence the mean value of each covariate X for inframarginal applications is $\mu_X^C = \frac{(\mu^{AT} + \mu^C) \cdot \mathbb{E}[X \mid \text{Apply}=1, \text{Treat}=1] - \mu^{AT} \cdot \mu_X^{AT}}{\mu^C}$.

We can estimate μ_X^{AT} and μ_X^C for each covariate X using combinations of sample averages and estimate the standard errors using the Delta method. We include stratification block fixed effects in all estimation and cluster standard errors by jobseeker.

⁴This method is a special case of the κ -weighting method proposed by [Abadie \(2003\)](#). We do not need to use Abadie’s more general method because this special case works for the problem we study – covariate means for compliers with a binary treatment and binary instrument.

C.4 Additional Tests of the Conceptual Framework

The conceptual framework delivers three additional predictions that we can test. In this appendix, we describe each prediction, explain how we test it, and show that the test results are consistent with the predictions of the conceptual framework. This is the detailed version of the argument summarized in Section 4.2 of the paper.

Prediction 1: Control group jobseekers will not apply to some high-value matches. This prediction follows from the framework’s assumption that some jobseekers face high enough application costs during some matching rounds that they will apply to no vacancies in these rounds. To test this, we consider two proxies for the value of a match: the salary, an admittedly narrow proxy but one that is easily interpretable and valued by all jobseekers; and the inverse covariance-weighted average of many positive attributes of a match (e.g. salary, benefits, commute distance) that is defined in Section 3.2. For each of the two proxies, we divide matches into quintiles and calculate the share of matches in each quintile that receive applications from control group jobseekers.

We find robust evidence that control group jobseekers miss applying to many high-value matches. Figure C.2 panel A shows the control group application rate by quintiles of the vacancy salary in blue. The application rate increases monotonically from the bottom to the top quintile, consistent with the idea that jobseekers value higher salaries. But under half of all control group applications are sent to top quintile matches, and under 0.1% of matches in the top quintile receive applications. Panel B shows the same pattern for quintiles based on the index of match value. Figure C.3 shows the same pattern using the within-jobseeker between-vacancy distributions of salary and the index, which accounts for the fact that different jobseekers may receive matches with systematically different values.

We provide a further test that takes advantage of the way the platform often sends multiple matches to a jobseeker simultaneously. Matches are sent to jobseekers roughly every month, as part of a matching round. Any jobseeker who has received multiple matches in that round receives a *batch* of multiple matches. Roughly two thirds of matches are sent in batches and one third are sent individually. Figure C.4 shows that the phone call treatment shifts the number of applications that respondents make in each of these rounds. Panel A shows the full distribution, while Panel B shows the distribution conditional on a positive number of applications. The conditional distributions are similar between treatment and control groups, with confidence intervals fully overlapping. This shows that the entire treatment effect on applications comes from the shift from applying to zero vacancies in a given round to a positive number of applications. This pattern is consistent with the conceptual framework: some jobseekers miss applying to some batches of matches due to temporarily high present bias or psychological application costs. If, instead, treatment shifted some jobseekers from making one to making two or more applications within a batch of matches,

this would not be explained by a reduction in the psychological cost of initiating applications.

Prediction 2: Treatment and control group applications will go to matches with similar average values. This prediction follows from the framework’s prediction that when returns to marginal and inframarginal applications are roughly equal, then treatment will induce applications to a mix of higher- and lower-return matches whose average value is similar to the control group.⁵

We find robust evidence that treatment and control group applications go to matches with similar average values. To test this, Figure C.2 panel A shows the control and treatment group application rates by quintiles of the vacancy salary in respectively blue and red. Treatment effects increase monotonically from the bottom to the top quintile. But the share of total applications sent to each quintile does not differ between treatment and control groups. To show this, we test whether the ratio of the treatment group application rate to the control group application rate is equal across all five quintiles and fail to reject the null hypothesis ($p = 0.774$). We see a similar pattern over many different ways of defining the value of matches, in each case reporting the results of the equal ratio tests in the footnotes below each figure. Figure C.2 Panel B shows the same pattern for quintiles based on the index of match value. Figure C.3 shows the same pattern using the within-jobseeker between-vacancy distributions of salary and the index. Figure C.5 shows a similar pattern when we collapse the data to the batch level (jobseeker $\times$ matching round), rather than the match level (jobseeker $\times$ vacancy). Finally, Figure C.6 shows a similar pattern when we measure the value of a batch based on the highest-value match in the batch, rather than the average values of the matches in the batch.

We provide a further test of this prediction using the complier / latent type method introduced in Appendix C.3. This allows us to estimate the mean characteristics of matches receiving marginal applications (i.e. applications submitted if and only if the jobseeker is treated) and of matches receiving inframarginal applications (i.e. applications submitted even if the jobseeker is not treated). Table C.5 shows that there are some differences between mean values of observed characteristics between marginal and inframarginal applications but these differences do not show consistently higher values for marginal or for inframarginal applications. For example, marginal applications are directed to jobs that offer slightly lower salaries, but are more likely to offer flexible hours. We find no difference between the mean values of the summary index V_{vm} between marginal and inframarginal applications.

We extend the test in the preceding paragraph to show that marginal and inframarginal applications also go to matches with similar probabilities of yielding interviews. To do so, we estimate latent interview probabilities using a data-driven approach and then use the latent type method

⁵Technically, this prediction holds in the special case of the framework where returns to marginal and inframarginal applications are equal, as we see in our data. When returns to marginal and inframarginal returns differ, then treatment and control applications may be sent to vacancies with different average values, as we explain in Appendix C.2.

described in the previous paragraph to compare latent probabilities between the inframarginal and marginal applications. Specifically, we first restrict the sample to the set of applications from control group jobseekers, i.e. jobseeker $\times$ vacancy matches with $T = 0$ and $Apply = 1$. We then regress *Interview* on a vector of jobseeker, vacancy, and match characteristics using a logit LASSO and predict $\hat{P}|X_{jvm} = \hat{Pr}(Interview | Apply = 1, X_{jvm})$ for each match. This is the probability that an application to that match will produce an interview, given the observed characteristics of the jobseeker, vacancy, and match.⁶ Table C.5’s bottom panel shows that the mean probability is similar between marginal and inframarginal applications when estimated using only vacancy- and match-level characteristics or also including jobseeker characteristics. Finally, we interact each latent interview probability measure with the value index to create an omnibus proxy for PV . The final row of Table C.5 shows that the means of this omnibus proxy for marginal and inframarginal applications do not differ.

Prediction 3: Treatment group applications will go to matches with more dispersed values. This prediction follows from the framework’s prediction that marginal applications that are submitted by jobseekers who are already submitting inframarginal applications in that period will go to matches with lower values, as evidenced by the wider range of PV in the pink+blue region than the pink-only region of Figure 1. To test this, we estimate treatment effects on the variance and 10th percentile of log salary for matches that receive applications, using a nonparametric bootstrap clustered by jobseeker to obtain standard errors on these treatment effects. Table C.6 shows treatment has a non-negative effect on the variance and a negative effect on the 10th percentile for both log salary and the proxy index V_{vm} that combines multiple proxies for match and vacancy value, although treatment effects for the index are not statistically significant. This qualitatively matches the model predictions but the effects are small and not close to statistically significant, giving limited support for the prediction that treatment leads to greater dispersion in salaries.

⁶This approach assumes that the relationship between interviews and observed characteristics does not differ for marginal and inframarginal applications, as we use the inframarginal applications for estimation and then predict out-of-sample to the marginal applications. This assumption is more reasonable in this application than many others because the platform observes and controls all information sent by the jobseeker to the firm.

Figure C.2: Heterogeneous Treatment Effects on Applications by Quintiles of Match Values

Panel A: Using Salary as a Proxy for Value

Panel B: Using the V_{vm} index as a Proxy for Value

Notes: This figure shows heterogeneous treatment effects of the phone call treatment on applications by quintiles of proxies for the value of the jobseeker $\times$ vacancy match to the jobseeker. Panel A uses the job posting salary as a value proxy and Panel B uses the V_{vm} index described in Section 3.2 as a value proxy. The p-value for the equal ratios test is 0.774 for Panel A and 0.869 for Panel B. Results in both panels are conditional on stratification block fixed effects. Each observation is a jobseeker $\times$ vacancy match and the sample includes all matches. Solid vertical lines show 95% confidence intervals, constructed using heteroskedasticity-robust standard errors, clustering by jobseeker.

Figure C.3: Heterogeneous Treatment Effects on Applications by Quintiles of the Within-Jobseeker Distribution of Match Values

Notes: This figure shows heterogeneous treatment effects of the phone call treatment on applications by quintiles of proxies for the value of the jobseeker $\times$ vacancy match to the jobseeker. Panel A shows heterogeneity by job posting salary, defining quintiles based on the distribution of salary within-jobseeker. Panel B shows heterogeneity by the V_{vm} index described in Section 3.2, again defining quintiles based on the distribution of salary within-jobseeker. The p-values for testing that the share of applications submitted to each quintile is equal between treatment groups is 0.701 in Panel A and 0.764 in Panel B. The unit of observation is the jobseeker $\times$ vacancy match. Results in both panels are conditional on stratification block fixed effects. Solid vertical lines show 95% confidence intervals, constructed using heteroskedasticity-robust standard errors, clustering by jobseeker.

Figure C.4: Treatment Effects on the Number of Applications per Jobseeker $\times$ Matching Round

Panel A: Treatment Effects on Each Positive Number of Applications

Panel B: Treatment Effects on Each Positive Number of Applications, Scaled by $\Pr(> 0 \text{ Applications})$

Notes: This figure shows treatment effects on the number of applications submitted per jobseeker $\times$ round. Estimation uses one observation per person-round, restricts the sample to jobseeker-rounds with at least two matches (65% of the data), conditions on stratification block fixed effects, and uses standard errors clustered by jobseeker. In Panel B, each estimate is multiplied by the probability of submitting > 0 applications so that the estimated effects for 1 and > 2 applications sum to one within each of the treatment and control groups. This allows us to show that treatment increases the number of job applications purely by increasing the number of rounds to which applications are submitted, rather than shifting the number of applications submitted within rounds to which jobseekers apply anyway.

Figure C.5: Heterogeneous Treatment Effects on Applications by Quintiles of Mean Batch Values

Notes: This figure shows heterogeneous treatment effects of the phone call treatment on applications by quintiles of proxies for the value of the jobseeker $\times$ vacancy match to the jobseeker. All analysis in this figure uses one batch (i.e. one jobseeker $\times$ matching round) as a unit of observation, *averaging over the values of the matches* in that batch. Panels A and B show heterogeneity by job posting salary and V_{vm} index described in Section 3.2 using the within-jobseeker between-vacancy distribution. The p-values for testing that the share of applications submitted to each quintile is equal between treatment groups is 0.351 in Panel A and 0.190 in Panel B. Results in both panels are conditional on stratification block fixed effects. Solid vertical lines show 95% confidence intervals, constructed using heteroskedasticity-robust standard errors, clustered by jobseeker.

Figure C.6: Heterogeneous Treatment Effects on Applications by Quintiles of Maximum Batch Values

Notes: This figure shows heterogeneous treatment effects of the phone call treatment on applications by quintiles of proxies for the value of the jobseeker $\times$ vacancy match to the jobseeker. All analysis in this figure uses one batch (i.e. one jobseeker $\times$ matching round) as a unit of observation, *taking the maximum of match values* in that batch. Panels A and B show heterogeneity by job posting salary and V_{vm} index described in Section 3.2 using the within-jobseekers between-vacancy distribution. The p-values for testing that the share of applications submitted to each quintile is equal between treatment groups is 0.062 in Panel A and 0.904 in Panel B. Results in both panels are conditional on stratification block fixed effects. Solid vertical lines show 95% confidence intervals, constructed using heteroskedasticity-robust standard errors, clustering by jobseeker.

Table C.5: Comparing Observed Characteristics of Inframarginal and Marginal Job Applications

	(1) Inframarginal applications	(2) Marginal applications	(3) Difference (p-value)
Firm characteristics			
Leave one out ratio of firm interviews to applications (on platform)	0.061	0.058	-0.003 (0.561)
Firm baseline ratio of interviews to applications (off-platform)	0.705	0.738	0.033 (0.053)
Firm # employees	88.347	43.720	-44.627 (0.001)
Firm # vacancies in last year	12.288	9.087	-3.201 (0.002)
Vacancy characteristics			
Ln(posted salary)	9.848	9.704	-0.143 (0.000)
< median working hours	0.651	0.625	-0.026 (0.306)
Allows employees to work flexible hours	0.697	0.803	0.106 (0.000)
Offers any benefits	0.767	0.758	-0.010 (0.624)
Match characteristics			
Exact education match vacancy requires high ed	0.168	0.265	0.097 (0.008)
Exact experience match vacancy requires experience	0.176	0.166	-0.011 (0.684)
Short commute	0.540	0.456	-0.083 (0.002)
Gender preference aligned	0.509	0.570	0.062 (0.012)
Posted ad salary > Jobseeker's stated expected salary	0.067	0.109	0.042 (0.186)
Predicted interview probabilities and value of vacancy			
$\hat{P} \mid X_{vm}$: Prob. interview vacancy and m	0.064	0.064	0.000 (0.891)
$\hat{P} \mid X_{jvm}$: Prob. interview jobseeker,	0.064	0.066	0.002 (0.613)
V_{vm} index: proxies of value of vacancy to jobseeker	0.266	0.277	0.012 (0.843)
$\hat{P} \mid X_{jvm} \times \ln(\text{posted salary})$	0.644	0.673	0.028 (0.529)
$\hat{P} \mid X_{jvm} \times V_{vm}$ index	0.239	0.243	0.003 (0.849)

Notes: Table shows the means of covariates for the inframarginal applications that are submitted irrespective of treatment status (column 1) and marginal applications that are submitted only if treated (column 2). Column 3 shows the difference between the covariate means for marginal and inframarginal applications. p-values reported in parentheses in column 3 are estimated using heteroskedasticity-robust standard errors clustered by jobseeker. The unit of observation is the jobseeker $\times$ vacancy match. Exact education match is an indicator for an exact match between the employer's preferred field of educational specialization and the jobseeker's field; this variable is conditional on vacancies requiring high education. Exact experience match is an indicator for a match in which the jobseeker has experience in the same occupation as the vacancy; this variable is conditional on vacancies requiring experience.

$\hat{P}$: All predicted interview probabilities have been estimated using logit LASSO specification, using applications from control group jobseekers. The logit LASSO model is allowed to select from the following characteristics. At the match level, high salary relative to respondent's matches; high salary relative to all matches; short commute (below median distance); jobseeker is overqualified relative to firm's minimum and preferential experience or educational requirements; jobseeker has an exact match of educational specialization for the job advert; jobseeker has an exact match of work experience for the job; and the job advert states preferring candidates from the jobseeker's gender. At the vacancy and firm level: industry classifications; vacancy occupation codes; work days for the vacancy; number of employees; total # of vacancies opened by the firm in the last year reported at baseline; minimum and maximum salary offered for the vacancy; $\ln(\text{salary net of commute cost})$; $\ln(\text{hourly salary})$; commute cost; vacancy offers a written employment contract; vacancy offers a permanent employment contract; total # of benefits offered by the vacancy; any benefits offered by vacancy; less than median working hours; whether the firm allows its employees to work flexible hours multiple times a week, once a week, multiple times a month, once a month, once after every few months or not at all; whether the firm is open to hiring women for the vacancy, number of positions to be filled; minimum years of experience and education required; any education required; any experience required; preferred years of experience; preferred years of experience in the same sector; firm provides pick and drop transport services to all, some or no employees; firm is located in a commercial, industrial or residential area; firm used web platform to advertise a vacancy at baseline; firm used third party outsourcing to advertise a vacancy at baseline; firm used newspaper to advertise a vacancy at baseline; whether CV drop-off was allowed at the firm's location at baseline; whether the firm reached out to its contacts to advertise a vacancy at baseline; whether the firm ever used newspaper to advertise a vacancy on platform or off platform at baseline; whether the firm ever used web platforms to advertise a vacancy on platform or off platform at baseline; whether the firm ever used third party outsourcing to advertise a vacancy on platform or off platform at baseline; years of education required for a vacancy posted by firm at baseline; an indicator for whether the firm either has no female employees and has no interest in hiring them, has no female employees but is open to hiring them, or has some female employees; total # of vacancies listed by the firm on platform; and firm baseline ratio of interviews to applications.

V_{vm} index: is an inverse covariance-weighted average constructed using vacancy and match level characteristics, defined in the note to Table 3.

Table C.6: Treatment Effects on Dispersion of Value of Matches Receiving Applications

	Ln(Salary)		V_{vm} index	
	Variance (1)	10th pctl (2)	Variance (3)	10th pctl (4)
Control	0.270 (0.020)	9.2 (0.010)	0.893 (0.056)	2.43 (0.032)
Treatment	0.272 (0.010)	9.2 (0.000)	0.965 (0.034)	2.39 (0.016)
Treatment effect	0.002 (0.022)	0.000 (0.010)	0.073 (0.065)	-0.034 (0.036)

Notes: This table shows how treatment changes the dispersion of the value of vacancies that receive applications, testing the model prediction that treatment should raise this dispersion. The table columns show dispersion statistics – variance and 10th percentile – of two proxies for vacancy value – log monthly salary and the index V_{vm} of vacancy- and match-level proxies for vacancy value defined in the note to Table 3. The table rows show the levels of these dispersion statistics for the treatment and control groups and the treatment effect. Standard errors are estimated using 1000 iterations of a nonparametric bootstrap, clustering by jobseeker.

C.5 Understanding Application Costs

This appendix provides detailed evidence about the types of application costs that are reduced by the main phone call treatment, expanding on the summary in Section 4.3 of the paper.

C.5.1 Pecuniary and Time Costs

Here we show results for the mechanism experiments described in Section 4.3 that reduce pecuniary and time costs of job applications on the platform. Column 1 of Table C.7 compares the effects of our main phone call treatment to the effects of a randomized text message reminder that the jobseeker can ask the platform to call them back about a job posting. This reminds the jobseeker that they can apply at near-zero pecuniary cost. The free callback reminder treatment has an effect one hundredth of the size of the effect of the main phone call treatment, and the two effects are statistically significantly different, suggesting a negligible role for pecuniary costs.

Column 2 of Table C.7 compares the effects of our main phone call treatment to the effects of randomly offering some control group jobseekers the option to text the platform and ask for a callback at a specific time. This eliminates the differential wait time between the main treatment and control groups. This callback request treatment has an effect one quarter of the size of the effect of the main phone call treatment, and the two effects are statistically significantly different, suggesting a limited role for time costs. Each column uses only the set of jobseeker $\times$ vacancy matches from rounds in which the relevant feature was randomized.

Table C.7: Treatment Effects on Applications of Reductions in Pecuniary and Time Costs

	Apply	
	(1)	(2)
Phone call treatment _{jt}	0.00342 (0.00145)	0.00226 (0.00047)
Free callback salience treatment _{jt}	0.00003 (0.00012)	
Callback request treatment _{jt}		0.00059 (0.00029)
# matches	13126	54135
# jobseekers	4423	7004
Mean outcome T = 0	0.00000	0.00030
P-value for equality of treatments	0.01742	0.00235
Round FE	Yes	Yes

Notes: Column 1 sample includes matches from jobseekers in the standard phone call treatment arm, jobseekers randomized into a free callback reminder, and the control group (mutually exclusive), from one round during which the mechanism experiment was active. Column 2 sample includes matches in the standard phone call treatment arm, a callback request treatment randomized at the person-round level, and the control group (mutually exclusive), from three rounds in which the experiment was active. The unit of observation is the jobseeker $\times$ vacancy match. Results are conditional on stratification block and round fixed effects. Heteroskedasticity-robust standard errors, clustered by jobseeker, are shown in parentheses.

C.5.2 Reminder Effects

Here we show results for the additional experiment and non-experimental analysis relating to reminder effects discussed in Section 4.3 of the paper. In principle, the phone call treatment’s positive effect on job applications be explained by a combination of procrastination and forgetfulness, as in [Ericson \(2017\)](#): some jobseekers may postpone applications until near the deadline, forget to submit some applications, and hence miss some high-value matches. Phone calls might provide reminders that reduce the share of forgotten applications.

But this reminder interpretation is inconsistent with the results from three mechanism tests. First, in three matching rounds, we send a second text message as a reminder to a random subsample of control group jobseekers, at the same time that the treatment group jobseekers get called. Table C.8 shows the effect of this reminder text message is one-fourteenth as large as the effect of the phone call treatment in the same matching rounds and statistically significantly smaller ($p < 0.001$).

Table C.8: Treatment Effects on Applications of Reminder Text Messages

	(1) Apply
Phone call treatment	0.00224 (0.00046)
Reminder text message treatment	0.00016 (0.00015)
# matches	54152
# jobseekers	7013
Mean outcome $T = 0$	0.00010
P-value for equality of treatment	0.00003

Notes: Table shows coefficients from regressing an indicator for job application on phone call treatment and eligibility for the reminder text message treatment. Sample includes matches in the standard phone call treatment arm, a reminder text message treatment which was randomized at the person-round level, and the control group (mutually exclusive), from three matching rounds during which the mechanism experiment was active. The phone call control group jobseekers eligible for the “crossover” treatment are coded as treated for the phone call treatment. The unit of observation is the jobseeker $\times$ vacancy match. The regression includes stratification block fixed effects. Heteroskedasticity-robust standard errors are shown in parentheses, clustered by jobseeker.

Second, we randomize the timing of the phone call within the period between sending the job alert text message and the application deadline. If the call functions as a reminder, treatment should have a larger effect for jobseekers called later, who have had more time to forget to apply. Instead, Table C.9 column 1 shows that treatment effects are smaller when phone calls occur later.

Third, we use non-experimental variation in the length of time between the job alert text message and the application deadline. This length of time is not randomly assigned, but varies due to logistical factors such as the number of call center agents on staff at the time of the matching round. We interact the duration of this window with treatment, controlling for quarter fixed effects to address variation over time in these logistical factors. Table C.9 column 2 shows the results. If reminder effects explained our results, we would expect treatment to have a larger effect when there is a longer application window, as jobseekers will have more time to forget to apply. Instead, treatment has a smaller effect when the window is longer.

Table C.9: Treatment Effects on Applications by Timing of Phone Call and Length of Application Window

	Apply	
	(1)	(2)
Phone call treatment	0.01379 (0.00090)	0.01616 (0.00100)
Phone call treatment $\times$ Days between job alert and first call assigned to jobseeker	-0.00018 (0.00010)	
Days between job alert and deadline		0.00005 (0.00002)
Phone call treatment $\times$ Days between job alert and deadline		-0.00072 (0.00004)
# matches	1116952	1005463
# jobseekers	9831	9011
Mean outcome T = 0	0.00185	0.00135
Round FE	Yes	No
Quarter SE	No	Yes

Notes: Column (1) shows coefficients from regressing an indicator for job application on phone call treatment and its interaction with days between job alert and first call assigned to the jobseeker. This variable is coded as zero for jobseekers in the control group. Column (2) shows coefficients from regressing an indicator for job application on phone call treatment, days between job alert and deadline, and the interaction of phone call treatment and days between job alert and deadline. The sample size is smaller in column (2) because the records of deadlines were not retained from some early matching rounds. All regressions include stratification block fixed effects. The unit of observation is the jobseeker $\times$ vacancy. Heteroskedasticity-robust standard errors are shown in parentheses, clustered by the jobseeker.

C.5.3 Encouragement and Pressure to Apply

Here we show results for the mechanism analysis relating to pressure and encouragement described in Section 4.3. In principle, the phone call treatment’s positive effect on job applications might be explained by jobseekers experiencing encouragement or pressure to apply from the phone calls.

But this explanation is inconsistent with three patterns in our data. First, call center agents are trained not to encourage or pressure jobseekers to apply, and regular audits of call recordings verified that they followed their scripts. This shows that jobseekers do not experience *explicit* encouragement or pressure. It remains possible that jobseekers feel *implicit* pressure because they have been called or because they are interacting with a person. But, second, if jobseekers feel implicit pressure, they do not respond in the lowest-cost way, which would be to apply for the first job listed on the call to end the call as quickly as possible. Instead, both treated and control group jobseekers send 31% of their job applications to vacancies listed first on their phone call or text message (Figure C.7). To help contextualize this result, we note that 22% of all vacancies are listed first on the call. So jobseekers are disproportionately likely to apply to first-listed vacancies, but this pattern does not differ between treated and control jobseekers.

Third, to further evaluate the potential role of implicit pressure, we study the within-jobseeker time series of responses to calls. If treated respondents did experience pressure to apply when called, they could easily avoid this pressure by not answering calls. In this scenario, jobseekers who answer calls in early rounds when they are learning about what it’s like to interact with the platform might be less likely to answer calls in subsequent rounds. To test for this potential negative relationship, we restrict the sample to the first 6 months of the experiment and regress an indicator for ‘answered the call in round T ’ on an indicator for ‘answered the call in round $T - 1$,’ controlling for observed jobseeker characteristics. Table C.10 column 1 shows jobseekers who picked up the previous call are 20 p.p. *more* likely to pick up the current call, rather than less likely. The relationship is very similar when we restrict to an even shorter period, 3 months (in column 2). Jobseekers could alternatively avoid pressure by answering phone calls and then saying they are unavailable to talk and immediately ending the call. But repeating this analysis using indicators for ‘answered the call and was willing to talk’ shows similarly positive relationships in the first 3 and 6 months of the experiment (column 3 & 4).

Figure C.7: Proportion of Applications by Order in which Vacancies are Listed

Notes: This figure shows the proportion of applications that jobseekers make to the first vacancy mentioned on the call versus vacancies mentioned second or later on the call. Sample consists of all applications (jobseeker $\times$ vacancy matches in which $Apply = 1$) in person-rounds in which the jobseeker receives at least two matches.

Table C.10: Response Persistence Between Periods

	Pickup Call		Available	
	(1)	(2)	(3)	(4)
Pickup call _{<i>t</i>-1}	0.20426 (0.00946)	0.22507 (0.03035)		
Available _{<i>t</i>-1}			0.18889 (0.00945)	0.19359 (0.02776)
# matches	13840	1474	13840	1474
# jobseekers	3534	922	3534	922
# jobseekers with outcome variation	2158	170	1773	181
Mean outcome Pickup _{<i>t</i>-1} = 0	0.35023	0.44396		
Mean outcome Available _{<i>t</i>-1} = 0			0.20996	0.32934
No of Months	First 6 months	First 3 months	First 6 months	First 3 months

Notes: Columns (1) and (2) show the relationship between call pickup in the previous and current matching rounds. “Pickup call” = 1 if anyone answered the phone call. Columns (3) and (4) show the relationship between availability in the previous and current matching rounds. “Available” = 1 if the target jobseeker was reached and was available to listen to their job matches. The unit of observation is jobseeker $\times$ round. The sample in all columns is restricted to jobseekers assigned to the phone call treatment group. Additionally, columns (1) and (3) focus on the first six months of the experiment, while columns (2) and (4) focus on the first three months. All specifications control for randomization block fixed effects and the following baseline jobseeker characteristics: age, gender, married, child, above-median education, any work experience, years of work experience, and number of occupations selected. Heteroskedasticity-robust standard errors, clustered by jobseeker, are reported in parentheses.

C.6 Evaluating Alternative Explanations

This appendix provides detailed evidence about the five alternative explanations for the effects main phone call treatment that we evaluate and largely reject. This expands on the summary in Section 4.4 of the paper.

C.6.1 What Types of Vacancies Receive Marginal & Inframarginal Applications?

The returns to marginal applications submitted due to the phone call treatment depend in part on the characteristics of vacancies and matches to which these are submitted. In principle, it might be possible that marginal applications and inframarginal applications might have roughly equal returns if marginal applications are sent to vacancies that are both systematically worse matches for the jobseekers (leading to lower interview probabilities) and systematically less competitive (leading to higher interview probabilities).

However, we show in Appendix C.4 that marginal and inframarginal applications are sent to vacancies and matches with very similar observed characteristics, including predicted probabilities of yielding interviews. This suggests this explanation is unlikely.

C.6.2 Which Jobseekers Submit Marginal & Inframarginal Applications?

The returns to marginal applications submitted due to the phone call treatment depend in part on the characteristics of jobseekers who submit each type of applications. In principle, it might be possible that marginal and inframarginal applications have roughly equal returns because each individual jobseeker experiences decreasing returns to additional search effort but treatment-induced applications come from jobseekers who are positively selected on education, experience, etc.

However, in this appendix we show that jobseekers who submit marginal and inframarginal applications have similar time-invariant characteristics using four methods. First, marginal and inframarginal applications come from jobseekers with similar observed characteristics. To show this, we use the same latent type analysis introduced in Appendix C.3. Table C.11 shows that mean education and CV quality scores (provided by firms, as discussed in Section 2.3) are almost identical for the jobseekers submitting marginal and inframarginal applications. Marginal applications come from jobseekers with slightly more work experience. But, as we show below, our main findings are unchanged when we control for experience.

Second, marginal and inframarginal applications come from jobseekers with similar latent interview probabilities. To show this, we estimate latent interview probabilities using a data-driven approach and then compare latent probabilities between the inframarginal and marginal applications. Specifically, we first restrict the sample to the set of applications from control group jobseekers, i.e. $\text{jobseeker} \times \text{vacancy}$ matches with $T = 0$ and $\text{Apply} = 1$. We then regress *Interview* on a vector of jobseeker characteristics using a logit LASSO and predict $\hat{P}|X_j = \hat{Pr}(\text{Interview} | \text{Apply} = 1, X_j)$ for each jobseeker j . This is the probability the jobseeker will get an interview if

she applies, given her observed characteristics. The final row of Table C.11 shows that the mean of this measure does not differ between marginal and inframarginal applications.

Third, our main findings hold when we include jobseeker fixed effects. To show this, we run a “crossover” experiment that randomly reassigns some control group jobseekers to the treatment group in some matching rounds. It allows us to replicate our main analysis with jobseeker fixed effects, using only within-jobseeker variation through time to identify treatment effects. Table C.12 shows that the results of this experiment are similar to our main results. In particular, we cannot reject equality of the interview rates or quality-adjusted interview rates for inframarginal applications and marginal applications submitted due to the crossover treatment ($p > 0.450$). 16% of jobseekers have at least one match affected, allowing precise estimation of the crossover treatment effect conditional on the fixed effects. But only 0.65% of matches are affected by this treatment, so it has almost no impact on our estimates of the overall treatment effect (Table C.13).

Fourth, controlling for time-invariant observed jobseeker characteristics leaves our main results unchanged, including the constant returns finding. To show this, we repeat our analysis of the main experiment using a double selection LASSO to control for an extensive set of jobseeker baseline characteristics, following Belloni et al. (2014). The point estimates and standard errors are almost identical (Table B.3, columns 1, 4 – 6).

These four results show that the roughly constant return to treatment-induced job search is not explained by treatment changing patterns of jobseeker selection into applications.

Table C.11: Comparing Observed Characteristics of Jobseekers Submitting Marginal and Inframarginal Applications

	(1) Inframarginal applications	(2) Marginal applications	(3) Difference (p-value)
Years of education	12.162	11.647	-0.516 (0.204)
Years of work experience	7.472	8.601	1.129 (0.102)
CV Score excellent	0.297	0.295	-0.002 (0.985)
CV Score good	0.386	0.366	-0.020 (0.826)
CV Score average or lower	0.317	0.338	0.021 (0.793)
$\hat{P} \mid X_j$: Prob. interview $\mid$ jobseeker characteristics	0.064	0.067	0.004 (0.258)

Notes: Table shows the means of covariates for the inframarginal applications that are submitted without treatment (column 1) and marginal applications that are submitted due to treatment (column 2). Column 3 shows the difference between the covariate means for marginal and inframarginal applications with p-values in parentheses, estimated using heteroskedasticity-robust standard errors clustered by jobseeker. The unit of observation is the jobseeker $\times$ vacancy match. The predicted interview probabilities in the final row are estimated using a logit LASSO specification with the sample of applications from the control group jobseekers. The logit LASSO model is allowed to select from the following baseline jobseeker characteristics: completed CV, total # of occupational preferences selected, greater than median number of occupational preferences selected, age, education level indicators, years of work experience, currently studying, any work experience, female, female and married, female and has children, female and has a child age < 5 , employed and searching, employed and not searching, searching and not employed, not employed and not searching, indicators for each reported job search method used, and expected salary less than 90th percentile of salaries the jobseeker is matched to on platform. The CV quality score variables are not included in the interview probability prediction because they are only observed for the 15% of jobseekers who are matched with vacancies for which the hiring managers shared their CV evaluations.

Table C.12: Treatment Effects on Job Search & Search Returns Using Jobseeker Fixed Effects

	(1) Apply	(2) Interview	(3) Int. $\times V_{vm}$	(4) Interview	(5) Int. $\times V_{vm}$
Randomly assigned to treatment in round t	0.00764 (0.00066)	0.00063 (0.00028)	0.00265 (0.00122)		
Apply				0.08274 (0.03423)	0.34667 (0.14808)
# matches	1,116,735	1,116,735	1,116,735	1,116,735	1,116,735
# jobseekers	9614	9614	9614	9614	9614
Mean outcome T = 0	0.00185	0.00011	0.00043	0.00011	0.00043
Mean outcome T = 0, Apply = 1				0.06100	0.23237
p: IV effect = mean T = 0, Apply = 1				0.536	0.450
IV strength test: F-stat				133.1	133.1
IV strength test: p-value				0.00000	0.00000
JS FE	Yes	Yes	Yes	Yes	Yes
Round FE	Yes	Yes	Yes	Yes	Yes

Notes: This table shows the results from replicating the analysis in Table 3 but including jobseeker and round fixed effects and replacing the time-invariant treatment indicator with an indicator variable for jobseeker $\times$ vacancy matches assigned to the “crossover” phone call treatment, which reassigned some control group jobseekers in some rounds to the phone call treatment group. This indicator is used as a regressor in columns (1) – (3) and as an instrument for applications in columns (4) – (5). Other than the jobseeker fixed effects and use of the crossover treatment indicator, all other sample definitions, regression specifications, and inference methods are identical to Table 3. Findings are qualitatively similar to those from analyzing the time-invariant phone call treatment.

Table C.13: Treatment Effects on Job Search & Search Returns, Controlling for Crossover Matches

	(1) Apply	(2) Interview	(3) Int. $\times V_{vm}$	(4) Interview	(5) Int. $\times V_{vm}$
Phone call treatment	0.01333 (0.00075)	0.00078 (0.00009)	0.00286 (0.00036)		
Apply				0.05872 (0.00513)	0.21484 (0.02153)
# matches	1,116,952	1,116,952	1,116,952	1,116,952	1,116,952
# jobseekers	9831	9831	9831	9831	9831
Mean outcome T = 0	0.00185	0.00012	0.00045	0.00012	0.00045
Mean outcome T = 0, Apply = 1				0.06381	0.24487
p: IV effect = mean T = 0, Apply = 1				0.587	0.428
IV strength test: F-stat				314.7	314.7
IV strength test: p-value				0.00000	0.00000

Notes: This table shows that the estimates in Table 3 are unchanged when we include in each regression an indicator variable for the random subset of control group matches that are reassigned to the treatment group in a subset of rounds. All other sample definitions, regression specifications, and inference methods are identical to Table 3.

C.6.3 Does Treatment Provide More Information About Matches?

In principle, the phone call treatment might provide information about specific jobs, leading to higher application rates and enabling jobseekers to target better-matched vacancies.

However, in this appendix we show four pieces of evidence that are not consistent with this mechanism. First, call center agents are trained to read precise scripts that contain the same information as in the text messages. Second, agents do not provide additional information about general labor market conditions or assessments of the individual jobseeker's prospects. They are not given this information by the platform and are trained not to tell jobseekers about any beliefs they hold. Regular audits of call recordings confirm high compliance with these two aspects of the training. See Figure A.3 for an explanation of the call structure.

Third, call center agents seldom provide information about specific jobs. In approximately 80% of matching rounds covering 72% of matches, we gave the call center agents no additional information beyond the content of the text message scripts. All our results hold when restricting the sample to these rounds: treatment increases the application rate by more than 600% and we cannot reject equal returns for marginal and inframarginal applications (Table C.14).⁷

Fourth, treatment and control group jobseekers are equally likely to receive job matches from the platform. In principle, it might be possible that jobseekers are more likely to receive phone calls than text messages. For example, text messages may sometimes be blocked or unread.⁸ To test this, we survey jobseekers to ask if they remember receiving a job match from the platform by either phone call or text message in the previous 14 or 30 days (recall period randomized). Treatment and control group respondents are equally likely to report receiving matches (Table C.15, column 1). This pattern also holds with the sample selection correction described in Appendix B.6 (Table C.15, column 2). The majority of jobseekers were not sent any matches by the platform in previous 14 or 30 days, because they did not match to any jobs in this period. This explains why the control group mean for reporting receiving matches is only 39%. To account for this pattern, we estimate treatment effects on reporting receiving matches controlling for actually being sent a match in at least one of the last two matching rounds. These treatment effects remain close to zero, with or without the sample selection correction (columns 3 & 4).⁹

⁷As an additional test, we record if the jobseeker asked for additional information on the call, irrespective of whether the call center agent could provide this information. Treatment effects on applications are positive on calls with and without requests for more information. This suggests that application effects are not driven by even requests for new information, let alone receiving new information. But this analysis should be viewed with caution because it involves splitting the sample by a post-treatment variable: the choice to ask for more information.

⁸We also test and find no difference in treatment effects between the 93% of respondents who indicated at registration that they were comfortable communicating with the platform by text message and the remaining 7%.

⁹These columns also show that jobseekers sent matches are 26 percentage points more likely to report receiving matches, a reassuring check on the quality of the survey data. We do not expect 100% of jobseekers sent matches in the last two matching rounds to report receiving them, for two reasons. First, the recall periods cover 14 or 30 days before the survey, while the two matching rounds cover roughly 60 days on average. Second, some measurement error in recall is natural: jobseekers may forget they received matches (and hence underreport receiving matches) or may forget the exact date they received them (which might lead to overreporting or underreporting receiving matches).

Table C.14: Treatment Effects on Job Search & Search Returns Excluding Matching Rounds when Call Center Agents had More Information About Vacancies

	(1) Apply	(2) Interview	(3) Int. $\times$ V	(4) Interview	(5) Int. $\times$ V
Phone call treatment	0.01739 (0.00097)	0.00083 (0.00009)	0.00308 (0.00038)		
Apply				0.04767 (0.00433)	0.17684 (0.01798)
# matches	801922	801922	801922	801922	801922
# jobseekers	9603	9603	9603	9603	9603
Mean outcome T = 0	0.00208	0.00008	0.00031	0.00008	0.00031
Mean outcome T = 0, Apply = 1				0.03708	0.14802
p: IV effect = mean T = 0, Apply = 1				0.18247	0.38299
IV strength test: F-stat				320.1	320.1
IV strength test: p-value				0.00000	0.00000

Notes: This table repeats the analysis reported in Table 3 excluding the 20% of matching rounds when the call center agents had more information available about each vacancy and could provide that information to jobseekers. The results show that returns to marginal applications are still roughly constant when jobseekers cannot use the phone calls to get more information about the vacancies.

Column 1 shows the coefficient from regressing an indicator for job application on treatment assignment. Column 2 shows the coefficient from regressing an indicator for interview invitation on treatment assignment. Column 3 shows the coefficient from regressing an indicator for interview invitation weighted by a proxy index for the value of the vacancy to the jobseeker, V_{vm} , on treatment assignment. Column 4 shows the coefficient from regressing an indicator for interview invitation on job application, instrumented by treatment assignment. Column 5 shows the coefficient from regressing an indicator for interview invitation weighted by the proxy index V_{vm} on job application, instrumented by treatment assignment. The proxy index V_{vm} is an inverse covariance-weighted average (following [Anderson 2008](#)) constructed using vacancy-level characteristics log salary and indicators for offering any non-salary benefits, below-median working hours, and allowing flexible hours as well as indicators for the match-level characteristics of vacancy salary exceeding the jobseeker's expected salary, below-median commuting distance, the jobseeker's educational specialization exactly matching the vacancy's preference, and the jobseeker's work experience exactly matching the vacancy's preference. Anderson-style indices, by construction, have zero means and hence some negative values. But multiplying the interview invitation indicator by a negative value would not produce sensible results. Hence we recenter the index so it has strictly positive values.

All regressions use one observation per jobseeker $\times$ vacancy match, include stratification block fixed effects, and use heteroskedasticity-robust standard errors clustered by jobseeker, which are shown in parentheses. The p-value is for a test of equality between the IV treatment effect and the mean interview rate for control group applications. The first-stage F-statistic and p-value are for the test of weak identification from [Kleibergen & Paap \(2006\)](#).

Table C.15: Treatment Effects on Recalling Receiving Matches

	Respondent reported receiving matches:			
	(1)	(2)	(3)	(4)
Phone call treatment	-0.01533 (0.02357)	0.00111 (0.03499)	-0.00691 (0.02277)	0.00373 (0.03302)
Platform sent match in last 2 rounds			0.25577 (0.02085)	0.25974 (0.02175)
# jobseekers	2177	14069	2177	14069
# responses T = 0	978	978	978	978
# responses T = 1	1199	1199	1199	1199
Mean outcome T = 0	0.38753	0.38753	0.38753	0.38753
IV strength test: F-stat		57.845		70.838
IV strength test: p-value		0.000		0.000
Adjusted for non-response	No	Yes	No	Yes

Notes: This table shows treatment effects on the probability that respondents report receiving matches from the platform from either a phone call or a text message. The recall period is randomized to 14 or 30 days. All jobseekers who responded to the survey were asked these questions, even if the platform did send them a recent match. Each outcome is regressed on an indicator for treatment assignment, an indicator for a 30-day recall period, and stratification block fixed effects. Even-numbered columns include selection adjustment terms for survey non-response described in Appendix B.6, following DiNardo et al. (2021). The first-stage F-statistics jointly test the strength of the four excluded instruments. The regressions in columns (3) and (4) control for an indicator equal to one if the platform sent a match to the jobseeker in the last 2 rounds, which cover roughly 2 months. Standard errors shown in parentheses. For columns without non-response adjustments, these are heteroskedasticity-robust and clustered by jobseeker. For columns with non-response adjustments, these are estimated using 500 iterations of a nonparametric bootstrap, clustered by jobseeker. The unit of observation is a survey response, as some jobseekers were surveyed twice, which explains why the sample sizes in columns (2) and (4) are larger than the number of jobseekers in the study. Only 0.6% of jobseekers complete two surveys.

C.6.4 Does Treatment Affect Jobseekers’ Beliefs About The Value of Applications?

In principle, the phone call treatment might increase the job application rate by changing jobseekers’ beliefs. For example, jobseekers might view a call from a professional recruiting service as a signal that platform firms are larger or wealthier and thus able to provide more benefits or opportunities for advancement (higher V), or as a signal that the firm sees her as a good fit for the job (higher P).

However, in this appendix we show two pieces of evidence that are not consistent with this mechanism. First, we directly test this explanation by collecting data on jobseekers’ beliefs about P and V and estimating treatment effects on these two belief measures. Translated from Urdu, these questions ask: “Suppose Job Talash sends you one hundred job ads in the next year. Based on your past experience with our job matching service, how many of these jobs do you think would be desirable for you?” and “Suppose you apply for all of these jobs that you think are desirable. How many do you think would make you an offer?” Our main treatment assignment is time-invariant, so these questions are asking jobseekers about jobs sent by the mode of communication used in their treatment group. We therefore use a jobseeker-level version of equation (1) to estimate treatment effects on these two belief measures. Table C.16 shows that treatment does not shift jobseekers’ answers to either of these questions. Jobseekers in the control group on average think that they will receive an offer from 43% of jobs they are interested in; the phone call treatment decreases this by 1.1 percentage points (standard error 1.8). Jobseekers in the control group on average think that 31% of the vacancies on the platform would be desirable for them; the phone call treatment decreases this by 0.7 p.p. (standard error 1.6). The even-numbered columns show that results are similar when we adjust for survey non-response using the same method described in Appendix B.6. The survey data show that treatment does not increase respondents’ perceptions of the average values of V or P on the platform, and hence cannot explain the treatment effect on applications.

Second, if phone calls influence job applications because a jobseeker views them as informative about the quality of a specific match, then phone calls should have larger effects on applications when the jobseeker views the phone call as unusual than when she views it as part of normal platform operations. We can test this idea using the “crossover” experiment described in Appendix C.6.2, which reassigns a random subset of control group respondents into the treatment group in a few rounds. The phone calls will seem more unusual for jobseekers receiving this temporary treatment. The treatment effect on applications is similar for the main and crossover treatments (Table C.12). This suggests that the phone call is unlikely to shift application decisions by signaling that these are unusually high-value matches.

Table C.16: Treatment Effects on Beliefs About Potential Returns to Search on Job Talash Platform

	% desirable jobs respondent believes would make an offer (P)		% of jobs respondent believes desirable (V)	
	(1)	(2)	(3)	(4)
Phone call treatment	-0.01082 (0.01775)	-0.02583 (0.02089)	-0.00662 (0.01593)	0.00164 (0.01861)
# jobseekers	2003	9483	2081	9483
# jobseekers answered T = 0	1191	1191	1238	1238
# jobseekers answered T = 1	812	812	843	843
Mean outcome T = 0	0.42681	0.42681	0.31339	0.31339
Adjusted for non-response	No	Yes	No	Yes
IV strength test: F-stat		145.679		140.017
IV strength test: p-value		0.000		0.000

Notes: This table shows treatment effects on beliefs collected as part of jobseeker followup surveys. Each outcome is regressed on an indicator for treatment assignment and stratification block fixed effects. Columns (2) and (4) include selection adjustment terms for survey non-response as described in Section B.6, following DiNardo et al. (2021). The unit of observation is the jobseeker. The first-stage F-statistics jointly test the strength of the four excluded instruments. Standard errors shown in parentheses. For columns without non-response adjustments, these are heteroskedasticity-robust. For columns with non-response adjustments, these are estimated using 500 iterations of a nonparametric bootstrap.

C.6.5 Random Search

In principle, our finding of roughly constant returns to treatment-induced search might be explained by a random search framework. If jobseekers were to apply to vacancies at random and the phone call treatment were to reduce the cost of applying, then treatment would increase the application rate and yield constant returns to marginal applications. Random job search may seem implausible. But it has been widely assumed in canonical search models, even if only as a simplifying benchmark (e.g. [Pissarides \(2000\)](#)). It may also be a reasonable approximation given empirical evidence that jobseekers have limited information about labor market conditions and match quality (e.g. [Behaghel et al. \(2023\)](#); [Belot et al. \(2018\)](#); [Kiss et al. \(2023\)](#)).

However, in this appendix we note two pieces of evidence that are not consistent with this interpretation. First, recall from Section 2.4 and Appendix [C.4](#) that applications are sent more often to vacancies with higher salaries and other positive attributes, showing that applications are not random.

Second, we run an additional experiment designed to induce random search in order to compare that to marginal search effort induced by the phone call treatment. Specifically, in 20% of rounds we randomize the order in which vacancies are listed on both text messages and phone calls, which encourages additional applications to the randomly-chosen vacancies that are listed first. Vacancies listed earlier might attract more applications because applying to them takes less time or because jobseekers interpret the ordering as a signal of job quality or attainability.

We find that listing vacancies first produces more applications with decreasing, rather than constant, returns. Table [C.17](#) shows that the probability of application is 0.4 p.p. higher for vacancies listed first instead of second or later (column 1). Moreover, the average interview probability for marginal applications submitted because the vacancy was listed first is 2.6% (column 4). This is substantially and statistically significantly lower than the 6.3% average interview probability for jobs listed second or later, and less than half the 5.9% interview probability for marginal applications submitted due to the phone call treatment. This contrast suggests that the main phone call treatment is not inducing random search, consistent with the fact that 69% of applications induced by the phone call are sent to vacancies listed second or later.¹⁰

The result of this experiment emphasizes that the return to marginal search depends on what causes the marginal search and how it is directed. The randomized order treatment causes marginal search that is roughly randomly directed and has sharply decreasing returns. The phone call treatment causes marginal search that is directed in similar ways to inframarginal search and has

¹⁰Results are similar if we use only the 20% of rounds with randomized order or use all rounds and control for firm fixed effects, as firm identifiers determined vacancy order in non-randomized rounds. Order of job listing is uncorrelated with job and jobseeker characteristics conditional on these fixed effects. Results are similar if we compare only the first job to all subsequent jobs or include order indicators. We restrict the sample to jobseeker $\times$ round units in which the jobseeker matched with more than one vacancy, which is necessary for variation in vacancy order.

roughly constant returns. This highlights that our constant returns finding is a consequence of the type of search induced by the phone calls, not inherent to this labor market or to these jobseekers.

Table C.17: Treatment Effects of Lowering Cost of Applying to Randomly Chosen Vacancies

	(1) Apply	(2) Interview	(3) Int. $\times V_{vm}$	(4) Interview	(5) Int. $\times V_{vm}$
Vacancy listed first in batch on phone call	0.00440 (0.00065)	0.00011 (0.00009)	0.00046 (0.00034)		
Apply				0.02550 (0.02062)	0.10551 (0.07716)
# matches	938,284	938,284	938,284	938,284	938,284
# jobseekers	9255	9255	9255	9255	9255
# vacancies	1317	1317	1317	1317	1317
Mean outcome T = 0	0.00627	0.00039	0.00144	0.00039	0.00144
Mean outcome T = 0, Apply = 1				0.06287	0.22944
IV strength test: F-stat				45.2	45.2
IV strength test: p-value				0.00000	0.00000

Notes: This table shows the effect of varying the relative marginal cost of applying to an individual vacancy within a round, by changing the order in which vacancies are listed on the application phone call. Column 1 shows the coefficient from regressing an indicator for job application on an indicator equal to 1 for a vacancy that is listed first in the call to the jobseeker during the round and 0 otherwise. Column 2 shows the coefficient from regressing an indicator for interview invitation on an indicator for vacancy listed first in the call. Column 3 shows the coefficient from regressing an indicator for interview invitation weighted by a proxy index for the value of the vacancy to the jobseeker, V_{vm} , on an indicator for vacancy listed first in the call. Column 4 shows the coefficient from regressing an indicator for interview invitation on job application, instrumented by vacancy listed first on the call. Column 5 shows the coefficient from regressing an indicator for interview invitation weighted by the proxy index for V_{vm} on job application, and instrumented by vacancy listed first on the call. See the note below Table 3 for a definition of V_{vm} . The p-value is for a test of equality between the IV treatment effect and the mean interview rate for control group applications. The first-stage F-statistic and p-value are for the test of weak identification from [Kleibergen & Paap \(2006\)](#). All columns: The sample is restricted to jobseeker- rounds with ≥ 2 matches, which includes 84% of all matches in the full sample. For the first part of the study, vacancy order was not fully randomized and varied by the first digit of the firm ID and subsequently. For the remainder of the study, vacancy order was randomized within the sets of high- and low-priority matches for the jobseeker based on relevant experience. As a result, all these regressions control for the first digit of firm ID and its interaction with the time period when job order was/was not randomized. The unit of observation is the jobseeker $\times$ vacancy match. Heteroskedasticity-robust standard errors are shown in parentheses, with two-way clustering by the jobseeker and vacancy. Mean outcomes are for the control group, i.e. vacancies listed second or later on the telephone call. The proportion of applications submitted to the first vacancy is 0.31.

D Additional Analysis on Spillover Effects

Increased search effort by some jobseekers may affect firms and other jobseekers. The sign of this effect is theoretically ambiguous. For firms, getting more applications can increase the probability of receiving an application from a well-matched applicant and hence making a hire. But it can also generate congestion costs if firms need to review many poorly-matched applications. For other jobseekers, competing against more applications can lead to crowd-out. But the magnitude of crowd-out may be small and offset if firms increase total hiring when they get more applications.

We can identify spillover effects using variation in the vacancy-level treatment rate: the share of users matched to each vacancy who are treated. This share is random because matches are determined by pre-treatment characteristics (education, work experience, and occupational preferences). Our approach is analogous to papers that study spillovers using variation in treatment intensity within geographic labor markets (e.g. [Blundell et al. \(2004\)](#); [Gautier et al. \(2018\)](#); [LaLive et al. \(2022\)](#)). This approach works well because this platform’s matching structure fully determines the set of platform users who can compete with each other for each vacancy. This approach is not feasible for jobseeker-facing experiments on most platforms, where users can search and apply for many different jobs. On such platforms, it is difficult to define how much each user is competing with other users without a full model of the job search process.

We first verify that the experiment generates enough variation across vacancies in the treatment rate to identify spillovers. The percentage of matches that are treated has interdecile range across vacancies of [0.38,0.56], interquartile range [0.43,0.53], and standard deviation 0.081 (shown in [Figure D.1](#)). Vacancies matched to fewer jobseekers mechanically have more dispersed treatment rates, due to small-sample variation. But even vacancies with above-median numbers of matched jobseekers have standard deviation 0.054 in their treatment rates.

We estimate spillover effects using two methods. Our first method tests whether jobseeker-level outcomes are sensitive to the fraction of competing jobseekers who are treated, closely following [Crepon et al. \(2013\)](#). We define TR_{jv} as the fraction of jobseekers matched to vacancy v who are treated, excluding jobseeker j . This measures the treatment rate for jobseekers potentially competing against j at vacancy v . We use match-level data to regress interview invitations on jobseeker-level treatment status, the treatment rate defined above and their interaction:

$$\text{Interview}_{jv} = T_j \cdot \beta_1 + TR_{jv} \cdot \beta_2 + T_j \cdot TR_{jv} \cdot \beta_3 + \mathbf{X}_v \cdot \Lambda + \mu_b + \epsilon_{jv}, \quad (7)$$

where $\mathbf{X}_v$ contains the number of jobseekers matched to vacancy v and vacancy-level factors that determine matches (e.g. occupation) and μ_b is a stratification block fixed effect. We cluster standard errors by both jobseeker and vacancy because treatment is assigned at the jobseeker level and most of the variation in TR_{jv} is across vacancies. Finding $\beta_2 < 0$ would be evidence of negative spillover effects on control group jobseekers, as it would show lower interview probabilities

Figure D.1: Variation in Treatment Rate Between Vacancies

Panel A: Density of Vacancy-Level Treatment Rate

Panel B: Mean of Vacancy-Level Treatment Rate by Number of Matches

Notes: This figure shows the variation between vacancies in the fraction of matched jobseekers who are treated. This variation is used to identify the spillovers analysis in Section 5. Panel A shows the density of treatment rates at the vacancy level. Panel B shows the results from a local linear regression of vacancy-level treatment rate against the number of jobseekers matched to each vacancy (solid blue line). This panel demonstrates that the vacancy-level treatment rate is not systematically related to vacancy size. It also shows the density of vacancy size (dashed red line) to illustrate the available variation.

when more competing jobseekers are treated. Finding $\beta_2 + \beta_3 < 0$ would be evidence of negative spillovers on treated jobseekers. This method has an intention-to-treat spirit, as it uses only information on treatment assignments and matches, not application decisions.

We do not find evidence of negative spillover effects using this first method. Estimates of β_2 and β_3 are both small and not statistically significant (Table D.1, column 1). To interpret their magnitude, we consider the effect on a jobseeker’s interview probability of moving from the 25th to 75th percentile of TR_{jv} , the treatment exposure rate. This effect is 0.005 percentage points for a control group jobseeker (standard error 0.011, $p = 0.660$) and -0.012 p.p. for a treatment group jobseeker (standard error 0.017, $p = 0.468$). As a benchmark, the effect of a jobseeker’s own treatment status on interview invitations is substantially larger: 0.077 p.p. (from Table 3).

Equation (7) imposes a linear relationship. But spillover effects might be nonlinear and only substantial at high treatment rates. To test this idea, we repeat the analysis replacing the vacancy-level treatment rate TR_{jv} with indicators for the middle and top terciles of TR_v . These effects are again close to zero for control or treatment group jobseekers (Table D.1, column 2).

We also estimate spillovers using the number of jobseekers matched to vacancy v who are treated, rather than the share of jobseekers matched to vacancy v who are treated. This measure has substantial variation, with an interdecile range of 226 to 1048. In these regressions we also replace the control for the total number of jobseekers matched to the vacancy with the number of control group jobseekers matched to the vacancy, to avoid including treated jobseekers in two regressors. We again find no evidence of a negative relationship: a vacancy exposed to the 75th percentile of the number of matched jobseekers who are treated rather than the 25th percentile would have a 0.121 percentage point higher treatment effect on interviews (standard error 0.058, $p = 0.038$).

Our second method tests if vacancy-level treatment effects vary with vacancy-level treatment rates, closely following Ferracci et al. (2014). For each of the 1,342 vacancies, we estimate the treatment effect on interview invitations, $\Delta\text{Interview}_v$, and the treatment rate for matched jobseekers, TR_v . We use these vacancy-level data points to estimate

$$\Delta\text{Interview}_v = TR_v \cdot \alpha + \mathbf{X}_v \cdot \Lambda + \varepsilon_v, \quad (8)$$

conditional on the same vacancy-level covariates $\mathbf{X}_v$ as the previous analysis. Finding $\alpha < 0$ would be evidence of negative spillover effects, as this would show a smaller treatment effect on each jobseeker’s interview probability at vacancies receiving more treatment-induced applications.

We do not find evidence of negative spillover effects using this second method. Instead, we find a positive but small estimate of α (Table D.1, column 3). To interpret the magnitude, we note that this coefficient implies that a vacancy exposed to the 75th percentile of the treatment rate TR_v rather than the 25th percentile would have a 0.018 percentage point higher treatment effect on interviews (standard error 0.011, $p = 0.097$). To test for a nonlinear relationship, we repeat

Table D.1: Spillover Effects Between Jobseekers

	Method 1: Match-level		Method 2: Vacancy-level	
	(1) Interview	(2) Interview	(3) Interview effect	(4) Interview effect
Treatment	0.00195 (0.00084)	0.00101 (0.00021)		
Treatment rate [†]	0.00068 (0.00156)			
Treatment X treatment rate [†]	-0.00245 (0.00174)			
Treatment rate [†] : mid tercile		0.00017 (0.00015)		
Treatment rate [†] : top tercile		0.00017 (0.00023)		
Treatment X treatment rate [†] : mid tercile		-0.00032 (0.00026)		
Treatment X treatment rate [†] : top tercile		-0.00031 (0.00026)		
Treatment rate			0.00194 (0.00117)	
Treatment rate: middle tercile				0.00025 (0.00021)

Outcome mean	0.0005	0.0005	0.0004	0.0004
Exposure regressor mean	0.4686		0.4748	
Exposure regressor SD	0.0561		0.0805	
p: treated terciles equal		0.393		
p: control terciles equal		0.505		
p: terciles equal				0.225
# observations	1116952	1116952	1342	1342

Notes: This table shows the results of tests for spillovers between jobseekers on interview invitations. Column (1) shows results from regressing match-level interview invitations on own treatment status, the fraction of other jobseekers matched to the same vacancy who are treated, and their interaction. Column (2) shows results from a regression that replaces the fraction of other jobseekers who are matched to the same vacancy with terciles for the middle and top terciles of this fraction. The *p*-values below the regression output are for tests of no spillovers onto treated jobseekers ('p: treated terciles equal') and control jobseekers ('p: control terciles equal'). Column (3) shows results from regressing vacancy-level treatment effects on interview invitations on vacancy-level fractions of matches that are treated. Column (4) shows results from regressing vacancy-level treatment effects on interview invitations on the middle and top terciles of vacancy-level fractions of matches that are treated. The *p*-value below the regression output is for a test that the treatment effects do not vary with treatment rate ('p: terciles equal'). All regressions condition on firm size and sector and vacancy occupation, posted salary, education and experience requirements, and number of matched jobseekers. Columns (1) and (2) also condition on stratification block fixed effects. Heteroskedasticity-robust standard errors are shown in parentheses, clustered by jobseeker and vacancy in columns (1) and (2). Outcome and treatment rate means are for the full sample. Variables marked with [†] are leave-one-out averages that omit the jobseeker's own values.

this analysis replacing the vacancy-level treatment rate TR_v with indicators for the middle and top terciles of TR_v . These coefficients are positive, although we cannot reject the null hypothesis that treatment effects are equal across all three terciles (Table D.1, column 4). A nonparametric regression of vacancy-level treatment effects on treatment rates also shows no evidence of negative spillovers (Figure D.2).

The lack of negative spillovers is consistent with descriptive patterns in vacancy-level outcomes. If firms did dislike congestion, then the relationship between application and interview numbers might be non-monotonic: a small increase in the number of applications might lead to more interview invitations but an extremely high number of applications might lead firms to ignore all applications and make no interview invitations. Instead, vacancy-level regressions show that both the number of interviews and the probability of interviewing any jobseeker are monotonically increasing in the number of applications (Table D.2).

What might explain the negligible spillover effects we find? Our design cannot directly answer this question, but we suggest five possible explanations. First, spillover effects might be avoided if firms hire more when they receive more applications above their reservation hiring quality. Carranza et al. (2021) and Fernando et al. (2021) show indirect evidence consistent with this mechanism. Second, more offers need not mechanically lead to crowd-out because firms on this platform report filling only 60% of vacancies, as on other platforms Fernando et al. (2021). Third, firms may not get enough total applications from the platform to generate meaningful congestion: the average vacancy on this platform receives only 0.8 applications from control group applicants and another 6 applications from treated applicants (with pooled interdecile range 0-18). Fourth, the fact that only 30% of applications come through the platform attenuates the scope for search effort increases on the platform to generate spillover effects. The average firm receives 6.8 applications via the platform, of which 6 are due to the search encouragement treatment, but it also receives 15.9 applications from outside the platform. Taking these factors together, it is possible that firms in this labor market receive too few suitable applications via the platform in the absence of treatment for crowd-out to be relevant, at least at the interview stage that we are able to observe.

Figure D.2: Relationship between Vacancy-Level Treatment Effects on Interviews and Treatment Rates

Notes: Figure shows the relationship between vacancy-level treatment effects on interviews and treatment rates, as a test for spillover effects on interview invitations. The figure is constructed by estimating the treatment effect on interview invitations separately for each of the 1,342 vacancies, estimating the share of jobseekers matched to each vacancy who are treated, and then regressing the former quantity on the latter using local linear regression. The dashed lines show 95% confidence intervals. The relatively flat slope of this regression is evidence against spillover effects: it shows that jobseekers' treatment effects on interviews do not depend on the share of other jobseekers matched to the vacancy who are treated, even though a higher treatment rate leads to more applications.

Table D.2: Descriptive Analysis of Application-Interview Relationship at the Vacancy Level

	# applications	# interviews			Any interview	
	(1)	(2)	(3)	(4)	(5)	(6)
# matches	0.01228 (0.00281)	0.00000 (0.00013)	0.00004 (0.00042)	-0.00012 (0.00014)	-0.00002 (0.00003)	-0.00003 (0.00003)
Treatment rate	12.53093 (6.69339)					
# applications		0.01280 (0.00416)	0.00968 (0.03311)		0.00097 (0.00118)	
# applications: mid tercile				0.28457 (0.05371)		0.09361 (0.02178)
# applications: top tercile				0.72627 (0.14198)		0.06752 (0.02664)
Outcome mean	6.7669	0.3887	0.3887	0.3887	0.1251	0.1251
IV strength test: F-stat			3.50			
IV strength test: p-value			0.061			
p: terciles equal				0.000		0.000
# vacancies	1342	1342	1342	1342	1342	1342

Notes: This table shows the relationship between the number of applications and interviews at the vacancy level, to contextualize the spillovers analysis in Section 5. Column (1) shows that vacancies get more applications if they are matched to more jobseekers and if more of these jobseekers are treated. Column (2) shows that vacancies that get more applications issue more interview invitations. Column (3) shows that the positive relationship between applications and interviews persists when we instrument the number of applications with the fraction of matched jobseekers who are treated, although the instrument is relatively weak and the second stage estimate is imprecise. Column (4) replicates column (2) but replaces the number of interviews with indicators for the middle and top terciles of the number of applications. Columns (5) and (6) replicate columns (2) and (4) but replace the number of interviews with an indicator for conducting any interviews as an outcome. Columns (2) and (4) - (6) provide non-experimental evidence against congestion effects: when the number of applications gets very high, firms do not issue fewer interview invitations or decline to interview any applicants. All regressions condition on firm size and sector and on vacancy occupation, salary, education and experience requirements, and number of matched jobseekers. The unit of observation is the vacancy. Heteroskedasticity-robust standard errors shown in parentheses.
